Volume F

CRYSTALLOGRAPHY OF BIOLOGICAL MACROMOLECULES

Edited by

E. ARNOLD, D. M. HIMMEL AND M. G. ROSSMANN

Second Edition

Published for
THE INTERNATIONAL UNION OF CRYSTALLOGRAPHY
by
John Wiley & Sons, Ltd

2011

Dedicated to
DAVID C. PHILLIPS

The editors wish to express their special thanks to David Phillips (Lord Phillips of Ellesmere) and Professor Louise Johnson for contributing an exceptional chapter on the structure determination of hen egg-white lysozyme. Although Chapter 25.1 describes the first structural investigations of an enzyme, the procedures used are still as fresh and important today as they were 45 years ago, and this chapter is strongly recommended to students of both crystallography and enzymology. Completion of this chapter was David's last scientific accomplishment only a few weeks before his death. This volume of *International Tables for Crystallography* is dedicated to the memory of David C. Phillips in recognition of his pivotal contributions to the foundations of the crystallography of biological macromolecules.

Advisors and Advisory Board

Advisors: J. Drenth, A Liljas. **Advisory Board:** U. W. Arndt, E. N. Baker, H. M. Berman, T. L. Blundell, M. Bolognesi, A. T. Brunger, C. E. Bugg, R. Chandrasekaran, P. M. Colman, D. R. Davies, J. Deisenhofer, R. E. Dickerson, G. G. Dodson, H. Eklund, R. Giegé, J. P. Glusker, S. C. Harrison, W. G. J. Hol, K. C. Holmes, L. N. Johnson, K. K. Kannan, S.-H. Kim, A. Klug, D. Moras, R. J. Read, T. J. Richmond, G. E. Schulz, P. B. Sigler,† D. I. Stuart, T. Tsukihara, M. Vijayan, A. Yonath.

Preface (M. G. Rossmann and E. Arnold) xxviii

Preface to the second edition (E. Arnold, D. M. Himmel and M. G. Rossmann) xxix

PART 1. INTRODUCTION 1

1.1. Overview (E. Arnold, D. M. Himmel and M. G. Rossmann) 1

1.2. Historical background (M. G. Rossmann) 5

- **1.2.1. Introduction** 5
- **1.2.2. 1912 to the 1950s** 5
- **1.2.3. The first investigations of biological macromolecules** 6
- **1.2.4. Globular proteins in the 1950s** 7
- **1.2.5. The first protein structures (1957 to the 1970s)** 8
- **1.2.6. Technological developments (1958 to the 1980s)** 9
- **1.2.7. Meetings** 10

1.3. Macromolecular crystallography and medicine (W. G. J. Hol and C. L. M. J. Verlinde) 13

- **1.3.1. Introduction** 13
- **1.3.2. Crystallography and medicine** 13
- **1.3.3. Crystallography and genetic diseases** 14
- **1.3.4. Crystallography and development of novel pharmaceuticals** 15
- **1.3.5. Vaccines, immunology and crystallography** 26
- **1.3.6. Outlook and dreams** 26

1.4. Perspectives for the future (E. Arnold, M. G. Rossmann, D. M. Himmel, J. C. H. Spence and S. Sun) 39

- **1.4.1. Gazing into the crystal ball (E. Arnold)** 39
- **1.4.2. Brief comments on *Gazing into the crystal ball* (M. G. Rossmann)** 40
- **1.4.3. Additional comments on *Gazing into the crystal ball* (D. M. Himmel)** 41
- **1.4.4. *Gazing into the crystal ball* – the X-ray free-electron laser (J. C. H. Spence)** 41
- **1.4.5. Electron microscopy's impact on structural biology (S. Sun)** 42

PART 2. BASIC CRYSTALLOGRAPHY 45

2.1. Introduction to basic crystallography (J. Drenth) 45

- **2.1.1. Crystals** 45
- **2.1.2. Symmetry** 46
- **2.1.3. Point groups and crystal systems** 47
- **2.1.4. Basic diffraction physics** 52
- **2.1.5. Reciprocal space and the Ewald sphere** 57
- **2.1.6. Mosaicity and integrated reflection intensity** 58
- **2.1.7. Calculation of electron density** 60
- **2.1.8. Symmetry in the diffraction pattern** 60
- **2.1.9. The Patterson function** 62

2.2. Quality indicators in macromolecular crystallography: definitions and applications (H. M. Einspahr and M. S. Weiss) 64

- **2.2.1. Introduction** 64
- **2.2.2. Quality indicators for diffraction data** 65
- **2.2.3. Comparing different diffraction data sets** 68
- **2.2.4. Quality indicators for substructure determination** 68
- **2.2.5. Quality indicators for phase determination** 69
- **2.2.6. Quality indicators for density modification and phase improvement** 69

2.2.7. Quality indicators for molecular replacement .. 70
2.2.8. Quality indicators for refinement .. 71
2.2.9. Quality indicators for the refined model .. 71
2.2.10. Error estimation for the refined model .. 73
2.2.11. The most commonly used quality indicators .. 73

PART 3. TECHNIQUES OF MOLECULAR BIOLOGY .. 75

3.1. Preparing recombinant proteins for X-ray crystallography (S. H. Hughes and A. M. Stock) .. 75
3.1.1. Introduction .. 75
3.1.2. Overview .. 75
3.1.3. Engineering an expression construct .. 76
3.1.4. Expression systems .. 77
3.1.5. Protein purification .. 85
3.1.6. Characterization of the purified product .. 88
3.1.7. Reprise .. 89

3.2. Expression and purification of membrane proteins for structural studies (J. A. Ernst, D. G. Yansura and C. M. Koth) .. 92
3.2.1. Introduction .. 92
3.2.2. A consensus strategy for membrane-protein expression .. 92
3.2.3. A consensus strategy for membrane-protein purification .. 93
3.2.4. Common purification pitfalls and prioritized alternative strategies .. 96
3.2.5. Summary .. 96

PART 4. CRYSTALLIZATION .. 99

4.1. General methods (C. Sauter, B. Lorber, A. McPherson and R. Giegé) .. 99
4.1.1. Introduction .. 99
4.1.2. Main parameters that affect crystallization of macromolecules .. 100
4.1.3. Crystallization arrangements and classical methodologies .. 104
4.1.4. Advanced crystallization methodologies .. 107
4.1.5. From the macromolecule to perfect crystals: the physics view .. 111
4.1.6. How to crystallize a new macromolecule: the structural biology view .. 113
4.1.7. The future of protein crystal growth .. 115

4.2. Crystallization of membrane proteins (H. Michel) .. 122
4.2.1. Introduction .. 122
4.2.2. Principles of membrane-protein crystallization .. 122
4.2.3. General properties of detergents relevant to membrane-protein crystallization .. 123
4.2.4. The ‘small amphiphile concept’ .. 125
4.2.5. Membrane-protein crystallization with the help of antibody Fv fragments .. 126
4.2.6. Membrane-protein crystallization using cubic bicontinuous lipidic phases .. 126
4.2.7. General recommendations .. 126

4.3. Application of protein engineering to enhance crystallizability and improve crystal properties (Z. S. Derewenda) .. 129
4.3.1. Introduction .. 129
4.3.2. Microscopic aspects of protein crystallization .. 129
4.3.3. Engineering proteins with enhanced solubility .. 130
4.3.4. Optimization of target constructs .. 131
4.3.5. The use of fusion proteins for crystallization .. 131
4.3.6. Noncovalent crystallization chaperones .. 132
4.3.7. Removal of post-translational modifications .. 133
4.3.8. Stabilization of protein targets .. 134
4.3.9. Surface-entropy reduction (SER) .. 134

4.3.10. Improvement of crystal quality 135

4.3.11. Conclusions 135

4.4. High-throughput X-ray crystallography (K. H. Choi) 140

4.4.1. Introduction 140

4.4.2. Design of multiple constructs: bioinformatics analysis of genome sequences 140

4.4.3. Cloning 140

4.4.4. Protein expression and purification 142

4.4.5. Crystallization 142

4.4.6. Synchrotron data collection 143

PART 5. CRYSTAL PROPERTIES AND HANDLING 145

5.1. Crystal morphology, optical properties of crystals and crystal mounting (H. L. Carrell and J. P. Glusker) 145

5.1.1. Crystal morphology and optical properties 145

5.1.2. Crystal mounting 148

5.2. Crystal-density measurements (E. M. Westbrook) 152

5.2.1. Introduction 152

5.2.2. Solvent in macromolecular crystals 152

5.2.3. Matthews number 152

5.2.4. Algebraic concepts 152

5.2.5. Experimental estimation of hydration 153

5.2.6. Methods for measuring crystal density 153

5.2.7. How to handle the solvent density 156

PART 6. RADIATION SOURCES AND OPTICS 159

6.1. X-ray sources (U. W. Arndt) 159

6.1.1. Overview 159

6.1.2. Generation of X-rays 159

6.1.3. Properties of the X-ray beam 162

6.1.4. Beam conditioning 164

6.2. Neutron sources (B. P. Schoenborn and R. Knott) 168

6.2.1. Reactors 168

6.2.2. Spallation neutron sources 172

6.2.3. Summary 175

PART 7. X-RAY DETECTORS 177

7.1. Comparison of X-ray detectors (S. M. Gruner, E. F. Eikenberry and M. W. Tate) 177

7.1.1. Commonly used detectors: general considerations 177

7.1.2. Evaluating and comparing detectors 178

7.1.3. Characteristics of different detector approaches 179

7.1.4. Future detectors 181

7.2. CCD detectors (M. W. Tate, E. F. Eikenberry and S. M. Gruner) 183

7.2.1. Overview 183

7.2.2. CCD detector assembly 183

7.2.3. Calibration and correction 184

7.2.4. Detector system integration 186

7.2.5. Applications to macromolecular crystallography 187

7.2.6. Future of CCD detectors 187

PART 8. SYNCHROTRON CRYSTALLOGRAPHY .. 189

8.1. Synchrotron-radiation instrumentation, methods and scientific utilization (J. R. Helliwell) .. 189
- **8.1.1. Introduction** .. 189
- **8.1.2. The physics of SR** .. 189
- **8.1.3. Insertion devices (IDs)** .. 190
- **8.1.4. Beam characteristics delivered at the crystal sample** .. 191
- **8.1.5. Evolution of SR machines and experiments** .. 192
- **8.1.6. SR instrumentation** .. 194
- **8.1.7. SR monochromatic and Laue diffraction geometry** .. 195
- **8.1.8. Scientific utilization of SR in protein crystallography** .. 197
- **8.1.9. Concluding remarks** .. 200

8.2. Laue crystallography: time-resolved studies (K. Moffat) .. 205
- **8.2.1. Introduction** .. 205
- **8.2.2. Principles of Laue diffraction** .. 205
- **8.2.3. Practical considerations in the Laue technique** .. 206
- **8.2.4. The time-resolved experiment** .. 208
- **8.2.5. Conclusions** .. 209

PART 9. X-RAY DATA COLLECTION .. 211

9.1. Principles of monochromatic data collection (Z. Dauter and K. S. Wilson) .. 211
- **9.1.1. Introduction** .. 211
- **9.1.2. The components of a monochromatic X-ray experiment** .. 211
- **9.1.3. Data completeness** .. 211
- **9.1.4. X-ray sources** .. 211
- **9.1.5. Goniostat geometry** .. 212
- **9.1.6. Basis of the rotation method** .. 213
- **9.1.7. Rotation method: geometrical completeness** .. 217
- **9.1.8. Crystal-to-detector distance** .. 221
- **9.1.9. Wavelength** .. 222
- **9.1.10. Lysozyme as an example** .. 222
- **9.1.11. Rotation method: qualitative factors** .. 223
- **9.1.12. Radiation damage** .. 225
- **9.1.13. Relating data collection to the problem in hand** .. 226
- **9.1.14. The importance of low-resolution data** .. 228
- **9.1.15. Data quality over the whole resolution range** .. 228
- **9.1.16. Strategies for automated data acquisition** .. 229
- **9.1.17. Final remarks** .. 229

9.2. Robotic crystal loading (T. Earnest and C. Cork) .. 231
- **9.2.1. Introduction** .. 231
- **9.2.2. Robotic sample loaders** .. 231
- **9.2.3. Conclusion** .. 233

9.3. X-ray diffraction imaging of whole cells (D. Shapiro) .. 234
- **9.3.1. Introduction** .. 234
- **9.3.2. Phase retrieval from single-particle diffraction data** .. 235
- **9.3.3. High-resolution imaging of yeast** .. 235
- **9.3.4. Conclusions** .. 237

PART 10. CRYOCRYSTALLOGRAPHY .. 241

10.1. Introduction to cryocrystallography (H. Hope and S. Parkin) .. 241

- **10.1.1. Cooling of biocrystals** .. 241
- **10.1.2. Beneficial effects of low temperature** .. 242
- **10.1.3. Principles of cooling equipment** .. 244
- **10.1.4. Operational considerations** .. 245
- **10.1.5. Concluding note** .. 247

10.2. Cryocrystallography techniques and devices (D. W. Rodgers) .. 249

- **10.2.1. Introduction** .. 249
- **10.2.2. Crystal preparation** .. 249
- **10.2.3. Crystal mounting** .. 250
- **10.2.4. Flash cooling** .. 252
- **10.2.5. Transfer and storage** .. 253

10.3. Radiation damage (E. F. Garman) .. 256

- **10.3.1. Introduction** .. 256
- **10.3.2. Cryocrystallography as a mitigation strategy** .. 256
- **10.3.3. Characteristics of radiation damage at cryotemperatures** .. 257
- **10.3.4. Understanding radiation damage** .. 258
- **10.3.5. Mitigating and correcting for radiation damage** .. 259
- **10.3.6. Using radiation damage** .. 260
- **10.3.7. Open questions** .. 260

PART 11. DATA PROCESSING .. 263

11.1. Automatic indexing of oscillation images (M. G. Rossmann) .. 263

- **11.1.1. Introduction** .. 263
- **11.1.2. The crystal orientation matrix** .. 263
- **11.1.3. Fourier analysis of the reciprocal-lattice vector distribution when projected onto a chosen direction** .. 263
- **11.1.4. Exploring all possible directions to find a good set of basis vectors** .. 264
- **11.1.5. The program** .. 265

11.2. Integration of macromolecular diffraction data (A. G. W. Leslie) .. 266

- **11.2.1. Introduction** .. 266
- **11.2.2. Prerequisites for accurate integration** .. 266
- **11.2.3. Methods of integration** .. 266
- **11.2.4. The measurement box** .. 267
- **11.2.5. Integration by simple summation** .. 267
- **11.2.6. Integration by profile fitting** .. 268

11.3. Integration, scaling, space-group assignment and post refinement (W. Kabsch) .. 272

- **11.3.1. Introduction** .. 272
- **11.3.2. Modelling rotation images** .. 272
- **11.3.3. Integration** .. 275
- **11.3.4. Scaling** .. 277
- **11.3.5. Post refinement** .. 277
- **11.3.6. Space-group assignment** .. 278

11.4. *DENZO* and *SCALEPACK* (Z. Otwinowski, W. Minor, D. Borek and M. Cymborowski) .. 282

- **11.4.1. Introduction** .. 282
- **11.4.2. Diffraction from a perfect crystal lattice** .. 282
- **11.4.3. Autoindexing** .. 283
- **11.4.4. Coordinate systems** .. 284

11.4.5. Experimental assumptions 285

11.4.6. Prediction of the diffraction pattern 288

11.4.7. Integration of diffraction maxima by profile fitting 289

11.4.8. Scaling – multiplicative corrections 289

11.4.9. Global refinement or post refinement 291

11.4.10. Merging – assessment of the error model and signal magnitudes in the data 291

11.4.11. Detector diagnostics 292

11.4.12. *HKL-2000* and *HKL-3000* 292

11.4.13. Final note 294

11.5. The use of partially recorded reflections for post refinement, scaling and averaging X-ray diffraction data (C. G. van Beek, R. Bolotovsky and M. G. Rossmann) 296

11.5.1. Introduction 296

11.5.2. Generalization of the Hamilton, Rollett and Sparks equations to take into account partial reflections 296

11.5.3. Selection of reflections useful for scaling 297

11.5.4. Restraints and constraints 297

11.5.5. Generalization of the procedure for averaging reflection intensities 298

11.5.6. Estimating the quality of data scaling and averaging 298

11.5.7. Experimental results 298

11.5.8. Conclusions 301

Appendix A11.5.1. Partiality model (Rossmann, 1979; Rossmann *et al.*, 1979) 301

11.6. *XDS* (W. Kabsch) 304

11.6.1. Functional specification 304

11.6.2. *XDS* 304

11.6.3. *XSCALE* 308

11.6.4. *XDSCONV* 309

11.6.5. Parallelization of *XDS* 309

11.6.6. Availability 310

11.7. Detecting twinning by merohedry (T. O. Yeates and Y. Tsai) 311

11.7.1. Introduction 311

11.7.2. Twinning by merohedry – considerations of lattice symmetry 311

11.7.3. Considerations of length scale and effects in reciprocal space 312

11.7.4. Extent of twinning: the twin fraction 312

11.7.5. Indications of twinning 312

11.7.6. Twinning tests based on overall intensity statistics 313

11.7.7. Tests for partial twinning based on comparison of twin-related reflections 314

11.7.8. Higher forms of twinning 315

11.7.9. Other kinds of disorder 315

11.7.10. Summary 315

PART 12. ISOMORPHOUS REPLACEMENT 317

12.1. The preparation of heavy-atom derivatives of protein crystals for use in multiple isomorphous replacement and anomalous scattering (D. Carvin, S. A. Islam, M. J. E. Sternberg and T. L. Blundell) 317

12.1.1. Introduction 317

12.1.2. Heavy-atom data bank 317

12.1.3. Properties of heavy-atom compounds and their complexes 318

12.1.4. Amino acids as ligands 320

12.1.5. Protein chemistry of heavy-atom reagents 321

12.1.6. Metal-ion replacement in metalloproteins 324

12.1.7. Analogues of amino acids 324

12.1.8. Use of the heavy-atom data bank to select derivatives 325

12.2. Locating heavy-atom sites (M. T. Stubbs and R. Huber) 327

12.2.1. The origin of the phase problem 327

12.2.2. The Patterson function 328

12.2.3. The difference Fourier 329

12.2.4. Reality 329

12.2.5. Special complications 330

PART 13. MOLECULAR REPLACEMENT 333

13.1. Noncrystallographic symmetry (D. M. Blow) 333

13.1.1. Introduction 333

13.1.2. Definition of noncrystallographic symmetry 333

13.1.3. Use of the Patterson function to interpret noncrystallographic symmetry 333

13.1.4. Interpretation of generalized noncrystallographic symmetry where the molecular structure is partially known 335

13.1.5. The power of noncrystallographic symmetry in structure analysis 336

13.2. Rotation functions (J. Navaza) 340

13.2.1. Overview 340

13.2.2. Rotations in three-dimensional Euclidean space 340

13.2.3. The rotation function 341

13.2.4. The locked rotation function 343

13.2.5. Other rotation functions 344

13.2.6. Concluding remarks 344

Appendix A13.2.1. Formulae for the derivation and computation of the fast rotation function 344

13.3. Translation functions (L. Tong) 347

13.3.1. Introduction 347

13.3.2. *R*-factor and correlation-coefficient translation functions 347

13.3.3. Patterson-correlation translation function 348

13.3.4. Phased translation function 349

13.3.5. Packing check in translation functions 349

13.3.6. The unique region of a translation function (the Cheshire group) 349

13.3.7. Combined molecular replacement 349

13.3.8. The locked translation function 350

13.3.9. Miscellaneous translation functions 350

13.4. Noncrystallographic symmetry averaging of electron density for molecular-replacement phase refinement and extension (M. G. Rossmann and E. Arnold) 352

13.4.1. Introduction 352

13.4.2. Noncrystallographic symmetry (NCS) 352

13.4.3. Phase determination using NCS 354

13.4.4. The *p*- and *h*-cells 354

13.4.5. Combining crystallographic and noncrystallographic symmetry 355

13.4.6. Determining the molecular envelope 356

13.4.7. Finding the averaged density 357

13.4.8. Interpolation 358

13.4.9. Combining different crystal forms 358

13.4.10. Phase extension and refinement of the NCS parameters 359

13.4.11. Convergence 359

13.4.12. *Ab initio* phasing starts 360

13.4.13. Recent salient examples in low-symmetry cases: multidomain averaging and systematic applications of multiple-crystal-form averaging 360

13.4.14. Programs 361

13.5. Molecular replacement with *MOLREP* (A. Vagin and A. Teplyakov) 364

13.5.1. Introduction 364

13.5.2. Program operation 364

13.5.3. Preparation of the search model 364

13.5.4. Preparation of the X-ray data 364

13.5.5. Rotational search 365

13.5.6. Positional search 365

13.5.7. Multi-copy search 365

13.5.8. Fitting the model into electron density 366

13.5.9. Distribution 366

PART 14. ANOMALOUS DISPERSION 367

14.1. Heavy-atom location and phase determination with single-wavelength diffraction data (B. W. Matthews) 367

14.1.1. Introduction 367

14.1.2. The isomorphous-replacement method 367

14.1.3. The method of multiple isomorphous replacement 368

14.1.4. The method of Blow & Crick 368

14.1.5. The best Fourier 369

14.1.6. Anomalous scattering 369

14.1.7. Theory of anomalous scattering 369

14.1.8. The phase probability distribution for anomalous scattering 370

14.1.9. Anomalous scattering without isomorphous replacement 371

14.1.10. Location of heavy-atom sites 371

14.1.11. Use of anomalous-scattering data in heavy-atom location 371

14.1.12. Use of difference Fourier syntheses 371

14.1.13. Single isomorphous replacement 371

14.2. Multiwavelength anomalous diffraction (J. L. Smith and W. A. Hendrickson) 373

14.2.1. Anomalous scattering factors 373

14.2.2. A phase equation for MAD 374

14.2.3. Diffraction ratios for estimating the MAD phasing signal 375

14.2.4. Experimental considerations 375

14.2.5. Data handling 376

14.2.6. Approaches to MAD phasing 376

14.2.7. Determination of the anomalous-scatterer partial structure 377

14.2.8. General anomalous-scatterer labels for biological macromolecules 377

14.3. Automated MAD and MIR structure solution (T. C. Terwilliger and J. Berendzen) 379

14.3.1. Introduction 379

14.3.2. MAD and MIR structure solution 379

14.3.3. Decision making and structure solution 379

14.3.4. The need for rapid refinement and phasing during automated structure solution 379

14.3.5. Conversion of MAD data to a pseudo-SIRAS form 379

14.3.6. Scoring of trial heavy-atom solutions 380

14.3.7. Automated MIR and MAD structure determination 381

14.3.8. Generation of model X-ray data sets 382

14.3.9. Conclusions 382

14.3.10. Software availability 382

PART 15. DENSITY MODIFICATION AND PHASE COMBINATION 385

15.1. Phase improvement by iterative density modification (K. Y. J. Zhang, K. D. Cowtan and P. Main) 385

15.1.1. Introduction 385
15.1.2. Density-modification methods 385
15.1.3. Reciprocal-space interpretation of density modification 393
15.1.4. Phase combination 394
15.1.5. Combining constraints for phase improvement 396
15.1.6. Statistical density-modification methods 398
15.1.7. Example 398

15.2. Model phases: probabilities, bias and maps (R. J. Read) 401

15.2.1. Introduction 401
15.2.2. Model bias: importance of phase 401
15.2.3. Structure-factor probability relationships 401
15.2.4. Figure-of-merit weighting for model phases 404
15.2.5. Map coefficients to reduce model bias 404
15.2.6. Estimation of overall coordinate error 404
15.2.7. Difference-map coefficients 405
15.2.8. Refinement bias 405

15.3. *DM/DMMULTI* software for phase improvement by density modification (K. D. Cowtan, K. Y. J. Zhang and P. Main) 407

15.3.1. Introduction 407
15.3.2. Program operation 407
15.3.3. Preparation of input data 407
15.3.4. Choice of modes 408
15.3.5. Code description 410

PART 16. DIRECT METHODS 413

16.1. *Ab initio* phasing (G. M. Sheldrick, C. J. Gilmore, H. A. Hauptman, C. M. Weeks, R. Miller and I. Usón) 413

16.1.1. Introduction 413
16.1.2. Normalized structure-factor magnitudes 415
16.1.3. Starting the phasing process 416
16.1.4. Reciprocal-space phase refinement or expansion (*shaking*) 417
16.1.5. Real-space constraints (*baking*) 418
16.1.6. Fourier refinement 419
16.1.7. Resolution enhancement: the ‘free lunch’ algorithm 419
16.1.8. Utilizing Pattersons for better starts 419
16.1.9. *Shake-and-Bake*: an analysis of a dual-space method in action 420
16.1.10. Applying dual-space programs successfully 422
16.1.11. Substructure solution for native sulfurs and halide soaks 425
16.1.12. Computer programs for dual-space phasing 426
16.1.13. Conclusions and the grand challenge 429

16.2. The maximum-entropy method (G. Bricogne) 433

16.2.1. Introduction 433
16.2.2. The maximum-entropy principle in a general context 433
16.2.3. Adaptation to crystallography 435

16.3. *Ab initio* phasing of low-resolution Fourier syntheses (V. Y. Lunin, A. G. Urzhumtsev and A. Podjarny) 437

16.3.1. Introduction 437
16.3.2. General features of low-resolution images 437
16.3.3. Low-resolution phasing 437

16.3.4. Phase generation and selection 438
16.3.5. Processing of the output 439
16.3.6. Conclusions and examples 441

PART 17. MODEL BUILDING AND COMPUTER GRAPHICS 443

17.1. Macromolecular model building and validation using *Coot* (P. Emsley, B. Lohkamp and K. Cowtan) 443
17.1.1. Introduction 443
17.1.2. Model building 443
17.1.3. Validation 445
17.1.4. Scripting 446
17.1.5. Discussion 446

17.2. Molecular graphics and animation (A. J. Olson) 448
17.2.1. Introduction 448
17.2.2. Background – the evolution of molecular graphics hardware and software 448
17.2.3. Representation and visualization of molecular data and models 449
17.2.4. Presentation graphics 454
17.2.5. Looking ahead 457

PART 18. REFINEMENT 459

18.1. Introduction to refinement (L. F. Ten Eyck and K. D. Watenpaugh) 459
18.1.1. Overview 459
18.1.2. Background 459
18.1.3. Objectives 459
18.1.4. Least squares and maximum likelihood 460
18.1.5. Optimization 460
18.1.6. Data 460
18.1.7. Models 461
18.1.8. Optimization methods 462
18.1.9. Evaluation of the model 464
18.1.10. Conclusion 464

18.2. Enhanced macromolecular refinement by simulated annealing (A. T. Brunger, P. D. Adams and L. M. Rice) 466
18.2.1. Introduction 466
18.2.2. Cross validation 466
18.2.3. The target function 467
18.2.4. Searching conformational space 468
18.2.5. Examples 470
18.2.6. Multi-start refinement and structure-factor averaging 471
18.2.7. Ensemble models 471
18.2.8. Conclusions 472

18.3. Structure quality and target parameters (R. A. Engh and R. Huber) 474
18.3.1. Purpose of restraints 474
18.3.2. Formulation of refinement restraints 475
18.3.3. Strategy of application during building/refinement 483
18.3.4. Future perspectives 483

18.4. Refinement at atomic resolution (Z. Dauter, G. N. Murshudov and K. S. Wilson) 485
18.4.1. The atomic model and a definition of atomic resolution 485
18.4.2. Data 487
18.4.3. Computational algorithms and strategies 488
18.4.4. Computational options and tactics 489

18.4.5. Features in the refined model 491

18.4.6. Quality assessment of the model 495

18.4.7. Relation to biological chemistry 495

18.4.8. Practical strategies 496

18.5. Coordinate uncertainty (D. W. J. Cruickshank) 499

18.5.1. Introduction 499

18.5.2. The least-squares method 500

18.5.3. Restrained refinement 501

18.5.4. Two examples of full-matrix inversion 502

18.5.5. Approximate methods 505

18.5.6. The diffraction-component precision index 506

18.5.7. Examples of the diffraction-component precision index 507

18.5.8. Luzzati plots 509

18.6. *CNS*, a program system for structure-determination and refinement (A. T. Brunger, P. D. Adams, W. L. DeLano, P. Gros, R. W. Grosse-Kunstleve, J.-S. Jiang, N. S. Pannu, R. J. Read, L. M. Rice and T. Simonson) 512

18.6.1. Introduction 512

18.6.2. The CNS language 512

18.6.3. Symbols and parameters 513

18.6.4. Statistical functions 513

18.6.5. Symbolic target function 514

18.6.6. Modules and procedures 515

18.6.7. Task files 516

18.6.8. HTML interface 516

18.6.9. Example: combined maximum-likelihood and simulated-annealing refinement 517

18.6.10. Conclusions 517

18.7. The *TNT* refinement package (D. E. Tronrud and L. F. Ten Eyck) 520

18.7.1. Scope and function of the package 520

18.7.2. Historical context 520

18.7.3. Design principles 520

18.7.4. Current structure of the package 522

18.7.5. Innovations first introduced in *TNT* 522

18.7.6. *TNT* as a research tool 523

18.7.7. Current status of *TNT* 523

18.8. *ARP/wARP* – automated model building and refinement (V. S. Lamzin, A. Perrakis and K. S. Wilson) 525

18.8.1. Refinement and model building are two parts of modelling a structure 525

18.8.2. Free-atom and hybrid models 525

18.8.3. *ARP/wARP* applications 526

18.8.4. Iterations 528

18.8.5. Applicability and requirements 528

18.9. Macromolecular applications of *SHELX* (G. M. Sheldrick) 529

18.9.1. Introduction 529

18.9.2. Experimental phasing with *SHELXC/D/E* 529

18.9.3. Macromolecular refinement using *SHELXL* 531

18.9.4. *SHELXPRO* – protein interface to *SHELX* 532

18.9.5. Distribution and support of *SHELX* 532

18.10. *PrimeX* and the Schrödinger computational chemistry suite of programs (J. A. Bell, Y. Cao, J. R. Gunn, T. Day, E. Gallicchio, Z. Zhou, R. Levy and R. Farid) 534

18.10.1. Introduction 534

18.10.2. Computational environment 534

18.10.3. Achieving the mission of *PrimeX* 535

18.10.4. *PrimeX* implementation and theory 536

18.10.5. Conclusion 538

18.11. *PHENIX*: a comprehensive Python-based system for macromolecular structure solution (P. D. ADAMS, P. V. AFONINE, G. BUNKÓCZI, V. B. CHEN, I. W. DAVIS, N. ECHOLS, J. J. HEADD, L.-W. HUNG, G. J. KAPRAL, R. W. GROSSE-KUNSTLEVE, A. J. MCCOY, N. W. MORIARTY, R. OEFFNER, R. J. READ, D. C. RICHARDSON, J. S. RICHARDSON, T. C. TERWILLIGER AND P. H. ZWART) 539

18.11.1. Foundations 539

18.11.2. Analysis of experimental data 540

18.11.3. Substructure determination, phasing and molecular replacement 540

18.11.4. Model building, ligand fitting and nucleic acids 541

18.11.5. Model, and model-to-data, validation 542

18.11.6. Structure refinement 543

18.11.7. Integrated structure determination 544

18.11.8. Conclusions 545

18.12. Structure determination in the presence of twinning by merohedry (T. O. YEATES AND M. R. SAWAYA) 548

18.12.1. Introduction 548

18.12.2. Detwinning based on observed intensities 548

18.12.3. Molecular replacement with twinning 548

18.12.4. Multiple isomorphous replacement and anomalous phasing with twinning 548

18.12.5. Atomic refinement with twinning 549

18.12.6. Detwinning on the basis of model $F_{\rm calc}$ values 550

18.12.7. Summary 550

PART 19. OTHER EXPERIMENTAL TECHNIQUES 553

19.1. Neutron crystallography: methods and information content (A. A. KOSSIAKOFF) 553

19.1.1. Introduction 553

19.1.2. Diffraction geometries 553

19.1.3. Neutron density maps – information content 553

19.1.4. Phasing models and evaluation of correctness 554

19.1.5. Evaluation of correctness 554

19.1.6. Refinement 555

19.1.7. $D_2O - H_2O$ solvent difference maps 555

19.1.8. Applications of $D_2O - H_2O$ solvent difference maps 555

19.2. Electron diffraction of protein crystals (W. CHIU) 557

19.2.1. Electron scattering 557

19.2.2. The electron microscope 557

19.2.3. Data collection 557

19.2.4. Data processing 558

19.2.5. Future development 561

19.3. Small-angle X-ray scattering (H. TSURUTA AND J. E. JOHNSON) 563

19.3.1. Introduction 563

19.3.2. Small-angle single-crystal X-ray diffraction studies 563

19.3.3. Solution X-ray scattering studies 564

19.4. Small-angle neutron scattering (D. M. ENGELMAN AND P. B. MOORE) 575

19.4.1. Introduction 575

19.4.2. Fundamental relationships 575

19.4.3. Contrast variation 577

19.4.4. Distance measurements 579

19.4.5. Practical considerations 580

19.4.6. Examples 580

19.5. Fibre diffraction (R. Chandrasekaran and G. Stubbs) 583

19.5.1. Introduction 583

19.5.2. Types of fibres 583

19.5.3. Diffraction by helical molecules 584

19.5.4. Fibre preparation 585

19.5.5. Data collection 585

19.5.6. Data processing 585

19.5.7. Determination of structures 586

19.5.8. Structures determined by X-ray fibre diffraction 588

19.6. Electron cryomicroscopy of biological macromolecules (T. S. Baker and R. Henderson) 593

19.6.1. Abbreviations used 593

19.6.2. Introduction: macromolecular structure determination using electron microscopy 593

19.6.3. Physics of electron scattering and radiation damage 593

19.6.4. Three-dimensional electron cryomicroscopy of macromolecules 595

19.6.5. Image processing and 3D reconstruction 601

19.6.6. Visualization, modelling and interpretation of results 604

19.6.7. Trends 605

19.7. Nuclear magnetic resonance (NMR) spectroscopy (K. Wüthrich) 615

19.7.1. Complementary roles of NMR in solution and X-ray crystallography in structural biology 615

19.7.2. A standard protocol for NMR structure determination of proteins and nucleic acids 615

19.7.3. Combined use of single-crystal X-ray diffraction and solution NMR for structure determination 617

19.7.4. NMR studies of solvation in solution 617

19.7.5. NMR studies of rate processes and conformational equilibria in three-dimensional macromolecular structures 618

19.8. Use of *SPIDER* and *SPIRE* in image reconstruction (A. Leith, W. Baxter and J. Frank) 620

19.8.1. Introduction 620

19.8.2. Basic philosophy of single-particle reconstruction 620

19.8.3. Implementation of single-particle reconstruction in *SPIDER* 621

19.8.4. Implementation of single-particle reconstruction in *SPIRE* 623

19.8.5. Conclusion 623

19.9. Four-dimensional cryo-electron microscopy at quasi-atomic resolution: *IMAGIC 4D* (M. van Heel, R. Portugal, A. Rohou, C. Linnemayr, C. Bebeacua, R. Schmidt, T. Grant and M. Schatz) 624

19.9.1. Introduction 624

19.9.2. The *IMAGIC* software system 624

19.9.3. *IMAGIC* '4D' processing/data format 624

19.9.4. Software parallelization 625

19.9.5. Full 2D (parallel) astigmatic contrast transfer function correction 625

19.9.6. Parallel automatic particle picking 625

19.9.7. Parallel multi-reference alignments and reference bias 626

19.9.8. MSA and its parallelization 626

19.9.9. Handling multiple 3D reconstructions in parallel 626

19.9.10. Angular reconstitution 4D refinements 627

19.9.11. Discussion 627

19.10. Single-particle reconstruction with *EMAN* (S. Ludtke) 629

19.10.1. Introduction 629

19.10.2. Overview of *EMAN* 629

19.10.3. Single-particle reconstruction 631

19.10.4. Evaluating the reconstruction 631

PART 20. ENERGY CALCULATIONS AND MOLECULAR DYNAMICS 633

20.1. Molecular-dynamics simulation of protein crystals: convergence of molecular properties of ubiquitin (U. Stocker and W. F. van Gunsteren) 633

20.1.1. Introduction 633

20.1.2. Methods 633

20.1.3. Results 634

20.1.4. Conclusions 640

20.2. Molecular-dynamics simulations of biological macromolecules (C. B. Post and V. M. Dadarlat) 642

20.2.1. Introduction 642

20.2.2. The simulation method 642

20.2.3. Potential-energy function 642

20.2.4. Empirical parameterization of the force field 644

20.2.5. Modifications in the force field for structure determination 644

20.2.6. Internal dynamics and average structures 644

20.2.7. Assessment of the simulation procedure 645

20.2.8. Effect of crystallographic atomic resolution on structural stability during molecular dynamics 645

PART 21. STRUCTURE VALIDATION 649

21.1. Validation of protein crystal structures (G. J. Kleywegt) 649

21.1.1. Introduction 649

21.1.2. Types of error 649

21.1.3. Detecting outliers 650

21.1.4. Fixing errors 651

21.1.5. Preventing errors 652

21.1.6. Final model 652

21.1.7. A compendium of quality criteria 652

21.1.8. Future 658

21.2. Assessing the quality of macromolecular structures (S. J. Wodak, A. A. Vagin, J. Richelle, U. Das, J. Pontius and H. M. Berman) 662

21.2.1. Introduction 662

21.2.2. Validating the geometric and stereochemical parameters of the model 662

21.2.3. Validation of a model *versus* experimental data 665

21.2.4. Atomic resolution structures 673

21.2.5. Concluding remarks 673

21.3. Detection of errors in protein models (O. Dym, D. Eisenberg and T. O. Yeates) 677

21.3.1. Motivation and introduction 677

21.3.2. Separating evaluation from refinement 677

21.3.3. Algorithms for the detection of errors in protein models and the types of errors they detect 677

21.3.4. Selection of database 679

21.3.5. Examples: detection of errors in structures 679

21.3.6. Summary 682

21.3.7. Availability of software 682

21.4. *PROCHECK*: validation of protein-structure coordinates (R. A. Laskowski, M. W. MacArthur and J. M. Thornton) 684

21.4.1. Introduction 684

21.4.2. The program 684

21.4.3. The parameters 684

21.4.4. Which parameters are best? 685

21.4.5. Input 686

21.4.6. Output produced 686

21.4.7. Other validation tools .. 686

21.5. *KiNG* and kinemages (V. B. Chen, J. S. Richardson and D. C. Richardson) .. 688

21.5.1. Introduction to aims and concepts .. 688

21.5.2. Uses of *KiNG* and kinemages .. 689

21.5.3. Making kinemages .. 692

21.5.4. Software notes .. 693

21.6. *MolProbity*: all-atom structure validation for macromolecular crystallography (V. B. Chen, W. B. Arendall, J. J. Headd, D. A. Keedy, R. M. Immormino, G. J. Kapral, L. W. Murray, J. S. Richardson and D. C. Richardson) .. 694

21.6.1. Summary of *MolProbity* flow and user interactions .. 694

21.6.2. Validation analyses .. 694

21.6.3. Correction of outliers .. 698

21.6.4. Other *MolProbity* utility functions .. 699

21.6.5. Discussion .. 700

21.6.6. *MolProbity* availability .. 701

PART 22. MOLECULAR GEOMETRY AND FEATURES .. 703

22.1. Protein geometry: volumes, areas and distances (M. Gerstein and F. M. Richards) .. 703

22.1.1. Introduction .. 703

22.1.2. Definitions of protein volume .. 703

Subject index 874

Preface

E. ARNOLD AND M. G. ROSSMANN

International Tables for Crystallography, Volume F, *Crystallography of Biological Macromolecules*, was commissioned by the International Union of Crystallography (IUCr) in recognition of the extraordinary contributions that knowledge of macromolecular structure has made, and will make, to the analysis of biological systems, from enzyme catalysis to the workings of a whole cell. The volume covers all stages of a crystallographic analysis from the preparation of samples using the techniques of molecular biology and biochemistry, to crystallization, diffraction-data collection, phase determination, structure validation and structure analysis. Although the book is written for experienced scientists, it is recognized that the modern structural biologist is more likely to be a biologist interested in structure than a classical crystallographer interested in biology. Thus, there are chapters on the fundamentals, history and current perspectives of macromolecular crystallography, as well as on the availability of useful programs and databases including the Protein Data Bank. Each chapter has been written by an internationally recognized expert.

Macromolecular crystallography is undergoing a revolution. Just as crystallography became central to the study of chemistry, macromolecular crystallography has become a core science in biology. Macromolecular crystallography has shaped our view of biological molecular structure, and is providing a broader understanding of biological ultrastructure and the molecular interactions in living systems. As reflected by the exponential increase in entries in the Protein Data Bank over the past decade, there has been an explosion in the number of macromolecular structures determined, the majority by X-ray crystallography. Knowledge of the sequences of entire genomes, from bacteria to human, has sparked a structural genomics effort that aims to determine 10 000 new macromolecular structures in the next decade. Crystallography is expected to yield the largest share of this new crop of structures. The field of macromolecular crystallography is still evolving rapidly, and capturing its essence in a single volume is a challenge. Therefore, the volume emphasizes durable knowledge, but also contains articles on somewhat more volatile topics.

This project had its inception when Ted Baker (at that time President of the IUCr) approached one of us (MGR) about writing a book on macromolecular crystallography for the IUCr. Not only were there already some excellent books that covered most aspects of the subject, but the breadth of the subject was now so vast that no single person could possibly be an expert in all relevant topics. After further exchanges of e-mails, MGR realized that the officers of the IUCr were tacitly assuming that he would be willing to carry out the advice he had given so freely. He then asked his former post-doc and coauthor of an earlier article on molecular replacement in Volume B of *International Tables*, Eddy Arnold, to help him get out of a tight corner. After some serious deliberations of his own, Eddy agreed to be co-editor.

Together we fleshed out an outline that was broader than MGR's original plan, which had focused largely on crystallographic theory and technique. We felt that it would be valuable to briefly cover related techniques beyond X-ray diffraction, as well as to give an overview of the current field of structural biology. Although basic crystallography is also presented in the other volumes of *International Tables*, chapters describing fundamental crystallographic principles and practices have been included in an attempt to make the volume as coherent and self-contained as possible. We established an advisory board, developed a list of required chapters and obtained promises of participation from potential authors. In a departure from the style of previous volumes of *International Tables*, which have fewer articles and authors, we sought contributions for nearly 100 articles from an even larger number of contributing authors. The members of the advisory board reviewed the proposed outline of chapters and authors. We were pleasantly surprised when so many experts generously agreed to write articles for this volume, and delighted that the vast majority fulfilled their promises.

Significant events punctuating the process were the 1996 and 1999 IUCr congresses. At the 1996 IUCr Congress in Seattle, we convened a meeting with many of the authors. There we described the overall project design and received valuable suggestions. At that time, we hoped that the volume could be completed by 1999. At the 1999 IUCr Congress in Glasgow, we reviewed the detailed contents of the volume at an open meeting on the volumes of *International Tables* under development. By that time, we had received most of the articles and typesetting began in late 1999. The complexities of handling a large number of articles from so many authors led to delays at a number of stages. Ultimately, the completion date became mid-2001.

We are especially grateful to the staff at the IUCr and at our own institutions for their dedicated help in bringing this project to fruition. At the IUCr, we thank Nicola Ashcroft for an outstanding job on overall production of the volume, and for her patient correspondence and attention to detail. We also thank Peter Strickland, Sue King, Theo Hahn, Uri Shmueli, Mike Dacombe and Ted Baker for their help in coordinating the project. At Purdue University, we thank Cheryl Towell and Sharon Wilder for constant assistance, and Fay Chen for editorial suggestions. At the Center for Advanced Biotechnology and Medicine and Rutgers University, we thank Susan Mazzocchi and Barbara Shaver for their help in handling correspondence and galley proofs from the authors.

We are also especially indebted to the authors for their generous contributions and for documenting relevant expertise. We also thank the advisors and the members of the advisory board for their help. We are saddened to note that Paul Sigler, a member of the advisory board, passed away during the project. Paul was a towering figure who, with his medical background, recognized the role structure plays in providing insights into fundamental chemical and biological processes.

Preface to the second edition

E. Arnold, D. M. Himmel and M. G. Rossmann

Ten years after the appearance of the first edition of *International Tables for Crystallography*, Volume F, *Crystallography of Biological Macromolecules*, we are pleased to present the second edition. Preparation of the second edition has reflected the continuing evolution of macromolecular crystallography. Eddy Arnold and Michael Rossmann were glad to have Daniel Himmel, an accomplished crystallographer with diverse knowledge, join this effort. The three of us brainstormed about how to update this volume most effectively, and decided to seek new articles in key areas of rapid growth and ask authors from the first edition if they wished to revise their chapters. We were delighted when so many internationally recognized experts again made generous contributions that brought the volume up to date.

In the past decade the field of macromolecular crystallography has spawned an ever-increasing array of spectacular biological structures. The amazing conquests have included the translational machinery, the ribosome, in various functional states; the transcription machinery, multisubunit cellular RNA polymerases; a multitude of membrane proteins; and many more viruses. The marriage of crystallography and cryo-electron microscopy, including electron tomography, enables a multiscale view of biological structure including macromolecular inventories of cells in three dimensions. Multiprotein complexes are more routinely studied, and small-angle X-ray scattering has grown in prominence as a complementary technique to single-crystal X-ray diffraction. Structural genomics projects have been knocking out representative structures from a wide variety of proteomes from all levels of life. Structure-based drug-design prospects and the general problem of understanding protein–ligand interactions have benefitted from the development of techniques such as fragment screening, where thousands of small-molecule fragments are systematically soaked into crystals to interrogate potential binding sites – a central tool in the emerging field of chemical genetics. Software packages continue to evolve to enable rapid and reliable structure solution, visualization and analysis. X-ray lasers are now a reality and perhaps in the future many complex structures will be solved and imaged using data sets measured from tiny microcrystals that diffract their heart out before being destroyed by the pulsed high-brilliance beams. When thinking about the next ten years, we can expect more of the unexpected.

We wish to thank Nicola Ashcroft for handling the majority of correspondence with authors, and for maximizing the efficiency and quality of the overall process, thereby keeping the production schedule under control. We also thank our many colleagues and friends whose advice was valuable in designing the plan for the second edition.

International Tables for Crystallography (2012). Vol. F, Chapter 1.1, pp. 1–4.

PART 1. INTRODUCTION

Chapter 1.1. Overview

E. Arnold, D. M. Himmel and M. G. Rossmann

Volume F is devoted to the crystallography of large biological molecules, complementing the existing volumes of *International Tables for Crystallography*. A background history of the subject is followed by a concise introduction to the basic theory of X-ray diffraction and other requirements for the practice of crystallography. Basic crystallographic theory is presented in greater depth in other volumes of *International Tables*. The information in the latter portions of Volume F is specifically related to macromolecular structure.

Chapter 1.2 presents a brief history of the field of macromolecular crystallography. This is followed by an article (Chapter 1.3) that describes many of the connections of crystallography with medicine and gives a look into the future possibilities of structure-based design of drugs, vaccines and other agents. Chapter 1.4 provides some personal perspectives on what the future may hold for crystallography and the other physical sciences, as well as how budding new technologies and breakthroughs in these fields may impact both the sciences and the world at large.

Chapter 2.1 introduces diffraction theory and fundamentals of crystallography, including concepts of real and reciprocal space, unit-cell geometry and symmetry. It is shown how scattering from electron density and atoms leads to the formulation of structure factors. The phase problem is introduced, as well as the basic theory behind some of the more common methods for its solution. As the field of macromolecular crystallography has grown and matured, a variety of metrics have evolved for monitoring the quality of data collection, data processing and structure determination. In some cases, disagreement has arisen over the best way to calculate some of these metrics or which ones are most useful for monitoring the progress of the crystallographic experiment. Chapter 2.2 provides a comprehensive compilation of the most commonly used indicators of quality, along with a definition for each. The application of some of these indicators to validate the refined crystal structure is addressed further in Part 21 (below).

Molecular biology has had a major impact in terms of accelerating progress in structural biology and remains a rapidly developing area. Chapter 3.1 is a primer on modern molecular-biology techniques for producing materials for crystallographic studies. Since large amounts of highly purified materials are required, emphasis is placed on approaches for efficiently and economically yielding samples of biological macromolecules suitable for crystallization. Chapter 3.2 extends this overview to methods for the expression and purification of membrane proteins for structural studies. These introductions to protein expression are complemented by Chapter 4.3, which describes the rapidly developing area of molecular-engineering approaches for obtaining high-quality crystals of biological macromolecules.

The basic theory and practice of macromolecular crystallization are described in Chapters 4.1 and 4.2. This, too, is a rapidly evolving area, with continual advances in theory and practice. It is remarkable to consider the macromolecules that have been crystallized. We expect macromolecular engineering, covered in Chapter 4.3, to play a central role in coaxing more macromolecules to form crystals suitable for structure determination in the future. These areas will be complemented by high-throughput crystallographic approaches, covered in Chapter 4.4. These include the expression of proteins in various organisms for their structure determination. The material in Part 4 is complemented by Part 5, which summarizes traditional properties of and methods for handling macromolecular crystals, as well as how to measure crystal density.

Part 6 gives a brief introduction to the theory and practice of generating X-rays and neutrons for diffraction experiments. Chapter 6.1 describes the theory of X-ray production from both conventional and synchrotron X-ray sources, as well as methods for defining the energy spectrum and geometry of X-ray beams. Numerous articles in the other volumes of *International Tables* go into greater depths. Chapter 6.2 describes the generation of neutron beams.

Part 7 describes common methods for detecting X-rays, with a focus on detection devices that are currently most frequently used, including storage phosphor image plate and charge-coupled device (CCD) detectors. This has been another rapidly developing area, particularly in the past two decades. A further article describing X-ray detector theory and practice is *International Tables* Volume C, Chapter 7.1.

Synchrotron-radiation sources have played a prominent role in advancing the frontiers of macromolecular structure determination in terms of size, quality and throughput. The extremely high intensity, tunable wavelength characteristics and pulsed time structure of synchrotron beams have enabled many novel experiments. Some of the unique characteristics of synchrotron radiation are being harnessed to help solve the phase problem using anomalous-scattering measurements, *e.g.* in multiwavelength anomalous diffraction (MAD) experiments (see Chapter 14.2). The quality of synchrotron-radiation facilities for macromolecular studies has been increasing rapidly, partly in response to the perceived value of the structures being determined. Many synchrotron beamlines have been designed to meet the needs of macromolecular experiments. Chapter 8.1 surveys many of the roles that synchrotron radiation plays in modern macromolecular structure determination. Chapter 8.2 summarizes applications of the age-old Laue crystallography technique, which has seen a revival in the study of macromolecular crystal structures using portions of the white spectrum of synchrotron X-radiation. Chapter 4.2 of *International Tables* Volume C is also a useful reference for understanding synchrotron radiation.

Chapter 9.1 summarizes many aspects of data collection from single crystals using monochromatic X-ray beams. Common camera-geometry and coordinate-system-definition schemes are given. Because most macromolecular data collection is carried out using the oscillation (or rotation) method, strategies related to this technique are emphasized. A variety of articles in Volume C of *International Tables* serve as additional references. With the

advent of modern synchrotron-radiation facilities that provide high-intensity beams and CCD detectors with rapid data readout, data collection has often become so rapid that the rate-limiting step in collecting a data set could very well be the time it takes the experimenter to mount the crystal manually, lock the hutch and begin to take X-ray exposures. The introduction of robotic crystal loading, covered in Chapter 9.2, makes it possible to mount and screen many more crystals, collecting and saving data from them, in the same amount of time, often with far less risk to the crystals. Chapter 9.3 summarizes another technology, coherent X-ray diffraction microscopy (CXDM), which is made possible by the brightness of third-generation synchrotron X-ray sources. Using this method, diffractive methods can be applied to image certain non-crystalline single particles to as high as 11 nm resolution. Single-particle phase retrieval theory is briefly presented, followed by the application of CXDM to the imaging of a yeast cell, a discussion of the ramifications of radiation damage and, finally, the use of stereoscopic viewing to access three-dimensional information.

The use of cryogenic cooling of macromolecular crystals for data collection ('cryocrystallography') has become the most frequently used method of crystal handling for data collection. Part 10 summarizes the theory and practice of cryocrystallography. Among its advantages are enhanced crystal lifetime and improved resolution. Most current experiments in cryocrystallography use liquid-nitrogen-cooled gas streams, though some attempts have been made to use liquid-helium-cooled gas streams. Although cryogenic temperatures substantially protect macromolecular crystals against radiation damage from the generation of free radicals, the problem of radiation damage has not been entirely eliminated. Methods continue to be explored to reduce the rate of radiation damage, such as the use of free-radical scavengers in cryoprotective solutions, or to correct reflections data sets for X-ray radiation dose. Methods have also been developed for utilizing radiation damage for phasing. Just a decade ago, it was still widely believed that many macromolecular crystals could not be studied successfully using cryocrystallography, or that the practice would be troublesome or would lead to inferior results. Now, crystallographers routinely screen for suitable cryoprotective conditions for data collection even in initial experiments, and often crystal diffraction quality is no longer assessed except using cryogenic cooling. However, some crystals have resisted attempts to cool them successfully to cryogenic temperatures. Thus, data collection using ambient conditions, or moderate cooling (from approximately −40 °C to a few degrees below ambient temperature), is not likely to become obsolete in the near future.

Part 11 describes the processing of X-ray diffraction data from macromolecular crystals. Special associated problems concern dealing with large numbers of observations, large unit cells (hence crowded reciprocal lattices) and diverse factors related to crystal imperfection (large and often anisotropic mosaicity, variability of unit-cell dimensions *etc.*). Various camera geometries have been used in macromolecular crystallography, including precession, Weissenberg, three- and four-circle diffractometry, and oscillation or rotation. The majority of diffraction data sets are collected now *via* the oscillation method and using a variety of detectors. Among the topics covered in Part 11 are autoindexing, intensity integration, space-group assignment, scaling, post refinement, and detection of merohedral twinning. Commonly used software packages for the indexing, integration, scaling and post refinement of crystallographic data are presented. The discussion of intensity integration in Chapter 11.2 includes a description of some of the strategies used by *MOSFLM* and *DENZO*. *DENZO* and *SCALEPACK*, which form the backbone of the *HKL2000* package, are described in detail in Chapter 11.4, and *XDS* is described in Chapter 11.6.

Part 12 describes the theory and practice of the isomorphous replacement method, and begins the portion of Volume F that addresses how the phase problem in macromolecular crystallography can be solved. The isomorphous replacement method was the first technique used for solving macromolecular crystal structures, and will continue to play a central role for the foreseeable future. Chapter 12.1 describes the basic practice of isomorphous replacement, including the selection of heavy-metal reagents as candidate derivatives and crystal-derivatization procedures. Chapter 12.2 surveys some of the techniques used in isomorphous replacement calculations, including the location of heavy-atom sites and use of that information in phasing. Readers are also referred to Chapter 2.4 of *International Tables* Volume B for additional information about the isomorphous replacement method.

Part 13 describes the molecular replacement method and many of its uses in solving macromolecular crystal structures. This part covers general definitions of noncrystallographic symmetry, the use of rotation and translation functions, and phase improvement and extension *via* noncrystallographic symmetry. The molecular replacement method is commonly used to solve macromolecular crystal structures where redundant information is present either in a given crystal lattice or among different crystals. In some cases, phase information is obtained by averaging noncrystallographically redundant electron density either within a single crystal lattice or among multiple crystal lattices. In other cases, atomic models from known structures can be used to help phase unknown crystal structures containing related structures. With the number and type of known protein structures rising exponentially in recent years (see Chapter 24.1), molecular replacement has become the most common way to solve phases for an unknown protein structure. Molecular-replacement phasing is often used in conjunction with other phasing methods, including isomorphous replacement and density-modification methods. *International Tables* Volume B, Chapter 2.3 is also a useful reference for molecular-replacement techniques.

Anomalous-dispersion measurements have played an increasingly important role in solving the phase problem for macromolecular crystals. Anomalous dispersion has long been recognized as a source of experimental phase information; for more than three decades, macromolecular crystallographers have been exploiting anomalous-dispersion measurements from crystals containing heavy metals, using even conventional X-ray sources. In the past two decades, synchrotron sources have permitted optimized anomalous-scattering experiments, where the X-ray energy is selected to be near an absorption edge of a scattering element. Chapter 14.1 summarizes applications of anomalous scattering using single wavelengths for macromolecular crystal-structure determination. The multiwavelength anomalous diffraction (MAD) technique, in particular, is used to solve the phase problem for a broad array of macromolecular crystal structures. In the MAD experiment, intensities measured from a crystal at a number of wavelengths permit direct solution of the phase problem, frequently yielding easily interpretable electron-density maps. The theory and practice of the MAD technique are described in Chapters 14.2 and 14.3.

Density modification, discussed in Part 15, encompasses an array of techniques used to aid solution of the phase problem *via* electron-density-map modifications. Recognition of usual density-distribution patterns in macromolecular crystal structures permits the application of such techniques as solvent flattening (disordered solvent regions have lower density), histogram matching (normal distributions of density are expected) and skeletonization (owing to the long-chain nature of macromolecules such as proteins). Electron-density averaging, discussed in Chapter 13.4, can be thought of as a density-modification technique as well. Chapter 15.1 surveys the general problem and practice of density modification, including a discussion of solvent flattening, histogram matching, skeletonization and phase-combination methodology. Chapter 15.2 discusses weighting of Fourier terms for calculation of electron-density maps in a more general sense, especially with respect to the problem of minimizing model bias in phase improvement. Electron-density modification techniques can often be implemented efficiently in reciprocal space, too. Chapter 15.3 summarizes the implementation of phase modification in the *DM/DMMULTI* software.

Part 16 describes the use of direct methods in macromolecular crystallography. Some 30 years ago, direct methods revolutionized the practice of small-molecule crystallography by facilitating structure solution directly from intensity measurements. As a result, phase determination of most small-molecule crystal structures has become quite routine. In the meantime, many attempts have been made to apply direct methods to solving macromolecular crystal structures. Prospects in this area are improving, but success has been obtained in only a limited number of cases, often with extremely high resolution data measured from small proteins. Chapter 16.1 surveys progress in the application of direct methods to solve macromolecular crystal structures, and Chapter 16.2 summarizes the application of the maximum-entropy method to crystallography. Chapter 16.3 explores techniques now being developed to extend *ab initio* phasing to low-resolution data.

The use of computer graphics for building models of macromolecular structures has facilitated the efficiency of macromolecular structure solution and refinement immensely (Part 17). Until just a little more than 20 years ago, all models of macromolecular structures were built as physical models, with parts of appropriate dimensions scaled up to our size! Computer-graphics representations of structures have made macromolecular structure models more precise, especially when coupled with refinement methods, and have contributed to the rapid proliferation of new structural information. With continual improvement in computer hardware and software for three-dimensional visualization of molecules (the crystallographer's version of 'virtual reality'), continuing rapid progress and evolution in this area are likely. The availability of computer graphics has also contributed greatly to the magnificent illustration of crystal structures, one of the factors that have thrust structural biology into many prominent roles in modern life and chemical sciences. Chapter 17.1 describes a graphics software product, *Coot*, now widely used by macromolecular crystallographers for visualization and real-space refinement of X-ray crystal structures. Chapter 17.2 surveys the field of computer visualization and animation of molecular structures, with a valuable historical perspective. Chapter 3.3 of *International Tables* Volume B is a useful reference for basics of computer-graphics visualization of molecules.

As in other areas of crystallography, refinement methods are used to obtain the most complete and precise structural information from macromolecular crystallographic data. The often-limited resolution and other factors lead to underdetermination of structural parameters relative to small-molecule crystal structures. In addition to X-ray intensity observations, macromolecular refinement incorporates observations about the normal stereochemistry of molecules, thereby improving the data-to-parameter ratio. Whereas incorporation of geometrical restraints and constraints in macromolecular refinement was initially implemented about 30 years ago, it is now generally a publication prerequisite that this methodology be used in structure refinement. Basic principles of crystallographic refinement, including least-squares minimization, constrained refinement and restrained refinement, are described in Chapter 18.1. Simulated-annealing methods, discussed in Chapter 18.2, can accelerate convergence to a refined structure, and are now widely used in refining macromolecular crystal structures. Structure quality and target parameters for stereochemical constraints and restraints are discussed in Chapter 18.3. High-resolution refinement of macromolecular structures, including handling of hydrogen-atom positions, is discussed in Chapter 18.4. Estimation of coordinate error in structure refinement is discussed in Chapter 18.5. Chapters 18.6 to 18.11 summarize computer programs and packages in common use for macromolecular structure determination, refinement and analysis. These program systems include the *Crystallography & NMR System* (*CNS*, Chapter 18.6), the *TNT* refinement package (Chapter 18.7), *ARP* and *wARP* for automated model construction and refinement (Chapter 18.8), *SHELX* (Chapter 18.9), *PrimeX* and the *Schrödinger* computational chemistry suite (Chapter 18.10), and *PHENIX* (Chapter 18.11). This part concludes with a description of methods for structure determination in the presence of merohedral twinning (Chapter 18.12).

Part 19 is a collection of short reviews of alternative methods for studying macromolecular structure. Each can provide information complementary to that obtained from single-crystal X-ray diffraction methods. In fact, structural information obtained from nuclear magnetic resonance (NMR) spectroscopy or cryo-electron microscopy is now frequently used in initiating crystal structure solution *via* the molecular replacement method (Part 13). Neutron diffraction, discussed in Chapter 19.1, can be used to obtain high-precision information about hydrogen atoms in macromolecular structures. Electron-diffraction studies of thin crystals are yielding structural information to increasingly high resolution, often for problems where obtaining three-dimensional crystals is challenging (Chapter 19.2). Small-angle X-ray (Chapter 19.3) and neutron (Chapter 19.4) scattering studies can be used to obtain information about shape and electron-density contrast even in noncrystalline materials, and are especially informative in cases of large macromolecular assemblies (*e.g.* viruses and ribosomes). Fibre diffraction (Chapter 19.5) can be used to study the structure of fibrous biological molecules. The combination of electron microscopy and crystallography is helping to bridge molecular structure and multi-molecular ultrastructure in living cells. Cryo-electron microscopy and high-resolution electron microscopy have been applied to the study of detailed structures of noncrystalline molecules of increasing complexity (Chapter 19.6). NMR spectroscopy has become a central method in the determination of small and medium-sized protein structures (Chapter 19.7), and yields unique descriptions of molecular interactions and motion in solution. Continuing breakthroughs in NMR technology are expanding greatly the size range of structures that can be studied by NMR. Part 19 concludes with descriptions of software packages in common use for data processing and image reconstruction of single particles using electron-microscopy techniques. These include *SPIDER* and *SPIRE* (Chapter 19.8), *IMAGIC 4D* (Chapter 19.9) and *EMAN* (Chapter 19.10).

Energy and molecular-dynamics calculations already play an integral role in many approaches for refining macromolecular structures (Part 20). Simulation methods hold promise for greater understanding of the time course of macromolecular motion than can be obtained through painstaking experimental approaches. However, experimental structures are still the starting point for simulation methods, and the quality of simulations is judged relative to experimental observables. Chapters 20.1 and 20.2 present complementary surveys of the current field of energy and molecular-dynamics calculations.

Structure validation (Part 21) is an important part of macromolecular crystal structure determination. Owing in part to the low data-to-parameter ratio and to problems of model phase bias, it can be difficult to correct misinterpretations of structure that can occur at many stages of structure determination. Chapters 21.1, 21.2 and 21.3 present approaches to structure validation using a range of reference information about macromolecular structure, in addition to observed diffraction intensities. Structure-validation methods are especially important in cases where unusual or highly unexpected features are found in a new structure. Software packages widely used for structure validation, as well as the detection and correction of errors in structures, are described in Chapters 21.4 (*PROCHECK*), 21.5 (*KiNG* and kinemages) and 21.6 (*MolProbity*).

Part 22 presents a survey of many methods used in the analysis of macromolecular structure. Since macromolecular structures tend to be very complicated, it is essential to extract features, descriptions and representations that can simplify information in helpful ways. Calculations of molecular surface areas, volumes and solvent-accessible surface areas are discussed in Chapters 22.1 and 22.2. Useful generalizations relating surface areas buried at macromolecular interfaces and energies of association have emerged. Chapter 22.3 surveys the occurrence of hydrogen bonds in biological macromolecules. This treatment is complemented by a description of solvent structure in Chapter 23.5, below. Electrostatic interactions in proteins are described in Chapter 22.4. The Cambridge Structural Database is the most complete compendium of small-molecule structural data; its role in assessing macromolecular crystal structures is discussed in Chapter 22.5. Databases for the deposition of macromolecular coordinates are the subject of Part 24, below.

Part 23 surveys current knowledge of protein and nucleic acid architecture. Proliferation of structural data has created problems for classification schemes, which have been forced to co-evolve with new structural knowledge. Methods and computational algorithms for the structural classification of various protein tertiary folds and the recognition of separate structural domains are reviewed in Chapters 23.1 and 23.2. Systematic aspects of ligand binding to macromolecules are discussed in Chapter 23.3. A survey of nucleic acid structure, geometry and classification schemes is presented in Chapter 23.4. Solvent structure in macromolecular crystals is reviewed in Chapter 23.5. Halogen interactions with small organic molecules have been known for some time now, but halogen interactions with macromolecules have only begun to gain recognition in recent years. These interactions tend to be unfamiliar and, at times, non-intuitive to the structural biologist. For example, an iodine or bromine atom (*i.e.*, of a ligand) might interact with the carbonyl oxygen atom of a protein without electronic repulsion, provided the geometry of the interaction allows the halogen atom to serve as a Lewis acid instead of the expected Lewis base. Our current understanding of halogen–macromolecule interactions and the geometric parameters within which they operate are reviewed in Chapter 23.6.

With the proliferation of macromolecular structures, it has been necessary to establish databases as international resources for rapid access to, and archival of, primary structural data. The Protein Data Bank (PDB), which for almost thirty years was the depository for protein crystal (and later NMR) structures, was first established at Brookhaven National Laboratory in the United States and later expanded into the worldwide PDB (wwPDB). The wwPDB is now run by the Research Collaboratory for Structural Bioinformatics (RCSB PDB) based in the United States with additional deposition centres: the Macromolecular Structure Database (MSD) at the European Bioinformatics Institute (EBI), now the Protein Data Bank in Europe (PDBe); the PDB Japan (PDBj); and the BioMagResBank (BMRB). Chapter 24.1 describes the organization and features of the wwPDB. The wwPDB permits ready access to the rapidly increasing store of macromolecular structural data *via* the Internet, as well as rapid correlation of structural data with other key life-sciences databases. The Nucleic Acid Database (NDB), containing nucleic acid structures with and without bound ligands and proteins, is presented in Chapter 24.2. The Biological Macromolecule Crystallization Database (BMCD), a repository for macromolecular crystallization data, is described in Chapter 24.3.

Chapter 25.1 provides a detailed history of the structure determination of lysozyme, the first enzyme crystal structure to be solved. This chapter serves as a guide to the process by which the lysozyme structure was solved. Although the specific methods used to determine macromolecular structures have changed, the overall process is similar and the reader should find this account entertaining as well as instructive.

Chapter 1.2. Historical background

M. G. Rossmann

1.2.1. Introduction

Crystallography ranks with astronomy as one of the oldest sciences. Crystals, in the form of precious stones and common minerals, have attractive properties on account of their symmetry and their refractive and reflective properties, which result in the undefinable quality called beauty. Natural philosophers have long pondered the unusual properties seen in the discontinuous surface morphologies of crystals. Hooke (1665) and Huygens (1690) came close to grasping the way repeating objects create discrete crystal faces with reproducible interfacial angles. The symmetry of mineral crystals was explored systematically in the 18th and 19th centuries by measuring the angles between crystal faces, leading to the classification into symmetry systems from triclinic to cubic and the construction of symmetry tables (Schoenflies, 1891; Hilton, 1903; Astbury *et al.*, 1935) – the predecessors of today's *International Tables*.

1.2.2. 1912 to the 1950s

It was not until the interpretation of the first X-ray diffraction experiments by Max von Laue and Peter Ewald in 1912 that it was possible to ascertain the size of the repeating unit in simple crystals. Lawrence Bragg, encouraged by his father, William Bragg, recast the Laue equations into the physically intuitive form now known as 'Bragg's law' (Bragg & Bragg, 1913). This set the stage for a large number of structure determinations of inorganic salts and metals. The discovery of simple structures (Bragg, 1913), such as that of NaCl, led to a good deal of acrimony, for crystals of such salts were shown to consist of a uniform distribution of positive and negative ions, rather than discrete molecules. These early structure determinations were based on trial and error (sometimes guided by the predictions of Pope and Barlow that were based on packing considerations) until a set of atomic positions could be found that satisfied the observed intensity distribution of the X-ray reflections. This gave rise to rather pessimistic estimates that structures with more than about four independent atomic parameters would not be solvable.

The gradual advance in X-ray crystallography required a systematic understanding and tabulation of space groups. Previously, only various aspects of three-dimensional symmetry operations appropriate for periodic lattices had been listed. Consequently, in 1935, the growing crystallographic community put together the first set of *Internationale Tabellen* (Hermann, 1935), containing diagrams and information on about 230 space groups. After World War II, these tables were enlarged and combined with Kathleen Lonsdale's structure-factor formulae (Lonsdale, 1936) in the form of *International Tables* Volume I (Henry & Lonsdale, 1952). Most recently, they have again been revised and extended in Volume A (Hahn, 2005).

Simple organic compounds started to be examined in the 1920s. Perhaps foremost among these is the structure of hexamethylbenzene by Kathleen Lonsdale (Lonsdale, 1928). She showed that, as had been expected, benzene had a planar hexagonal structure. Another notable achievement of crystallography was made by J. D. Bernal in the early 1930s. He was able to differentiate between a number of possible structures for steroids by studying their packing arrangements in different unit cells (Bernal, 1933). Bernal ('Sage') had an enormous impact on English crystallographers in the 1930s. His character was immortalized by the novelist C. P. Snow in his book *The Search* (Snow, 1934). By the mid-1930s, J. Monteath Robertson and I. Woodward had determined the structure of nickel phthalocyanine (Robertson, 1935) using the heavy-atom method. This was a major crystallographic success and perhaps the first time that a crystallographer had succeeded in solving a structure when little chemical information was available.

Another event which had a major impact was the determination of the absolute hand of the asymmetric carbon atom of sodium tartrate by Bijvoet (Bijvoet, 1949; Bijvoet *et al.*, 1951). By indexing the X-ray reflections with a right-handed system, he showed that the breakdown of Friedel's law in the presence of an anomalous scatterer was consistent with the asymmetric carbon atom having a hand in agreement with Fischer's convention. With that knowledge, together with the prior results of organic reaction analyses, the absolute hand of other asymmetric carbon atoms could be established. In particular, the absolute structure of naturally occurring amino acids and riboses was now determined.

Until the mid-1950s, most structure determinations were made using only projection data. This not only reduced the tremendous effort required for manual indexing and for making visual estimates of intensity measurements, but also reduced the calculation effort to almost manageable proportions in the absence of computing machines. However, the structure determination of penicillin (Crowfoot, 1948; Crowfoot *et al.*, 1949), carried out during World War II by Dorothy Hodgkin and Charles Bunn, employed some three-dimensional data. A further major achievement was the solution of the three-dimensional structure of vitamin B_{12} by Dorothy Hodgkin and her colleagues (Hodgkin *et al.*, 1957) in the 1950s. They first used a cobalt atom as a heavy atom on a vitamin B_{12} fragment and were able to recognize the 'corrin' ring structure. The remainder of the B_{12} structure was determined by an extraordinary collaboration between Dorothy Hodgkin in Oxford and Kenneth Trueblood at UCLA in Los Angeles. While Dorothy's group did the data collection and interpretation, Ken's group performed the computing on the very early electronic Standard Western Automatic Computer (SWAC). Additional help was made available by the parallel work of J. G. White at Princeton University in New Jersey. This was at a time before the internet, before e-mail, before usable transatlantic telephones and before jet travel. Transatlantic, propeller-driven air connections had started to operate only a few years earlier.

Many technical advances were made in the 1930s that contributed to the rapidly increasing achievements of crystallography. W. H. Bragg had earlier suggested (Bragg, 1915) the use of Fourier methods to analyse the periodic electron-density distribution in crystals, and this was utilized by his son, W. L. Bragg (Bragg, 1929*a*,*b*). The relationship between a Fourier synthesis and a Fourier analysis demonstrated that the central problem in structural crystallography was in the phase. Compu-

tational devices to help plot this distribution were invented by Arnold Beevers and Henry Lipson in the form of their 'Beevers–Lipson strips' (Beevers & Lipson, 1934) and by J. Monteath Robertson with his 'Robertson sorting board' (Robertson, 1936). These devices were later supplemented by the XRAC electronic analogue machine of Ray Pepinsky (Pepinsky, 1947) and mechanical analogue machines (McLachlan & Champaygne, 1946; Lipson & Cochran, 1953) until electronic digital computers came into use during the mid-1950s.

A. Lindo Patterson, inspired by his visit to England in the 1930s where he met Lawrence Bragg, Kathleen Lonsdale and J. Monteath Robertson, showed how to use F^2 Fourier syntheses for structure determinations (Patterson, 1934, 1935). When the 'Patterson' synthesis was combined with the heavy-atom method, and (later) with electronic computers, it transformed analytical organic chemistry. No longer was it necessary for teams of chemists to labour for decades on the structure determination of natural products. Instead, a single crystallographer could solve such a structure in a period of months.

Improvements in data-collection devices have also had a major impact. Until the mid-1950s, the most common method of measuring intensities was by visual comparison of reflection 'spots' on films with a standard scale. However, the use of counters (used, for instance, by Bragg in 1912) was gradually automated and became the preferred technique in the 1960s. In addition, semi-automatic methods of measuring the optical densities along reciprocal lines on precession photographs were used extensively for early protein-structure determinations in the 1950s and 1960s.

1.2.3. The first investigations of biological macromolecules

Leeds, in the county of Yorkshire, was one of the centres of England's textile industry and home to a small research institute established to investigate the properties of natural fibres. W. T. Astbury became a member of this institute after learning about X-ray diffraction from single crystals in Bragg's laboratory. He investigated the diffraction of X-rays by wool, silk, keratin and other natural fibrous proteins. He showed that the resultant patterns could be roughly classified into two classes, α and β, and that on stretching some, for example, wool, the pattern is converted from α to β (Astbury, 1933).

Purification techniques for globular proteins were also being developed in the 1920s and 1930s, permitting J. B. Sumner at Cornell University to crystallize the first enzyme, namely urease, in 1926. Not much later, in Cambridge, J. D. Bernal and his student, Dorothy Crowfoot (Hodgkin), investigated crystals of pepsin. The resultant 1934 paper in *Nature* (Bernal & Crowfoot, 1934) is quite remarkable because of its speed of publication and because of the authors' extraordinary insight. The crystals of pepsin were found to deteriorate quickly in air when taken out of their crystallization solution and, therefore, had to be contained in a sealed capillary tube for all X-ray experiments. This form of protein-crystal mounting remained in vogue until the 1990s when crystal-freezing techniques were introduced. But, most importantly, it was recognized that the pepsin diffraction pattern implied that the protein molecules have a unique structure and that these crystals would be a vehicle for the determination of that structure to atomic resolution. This understanding of protein structure occurred at a time when proteins were widely thought to form heterogeneous micelles, a concept which persisted another 20 years until Sanger was able to determine the unique amino-acid sequences of the two chains in an insulin molecule (Sanger & Tuppy, 1951; Sanger & Thompson, 1953*a*,*b*).

Soon after Bernal and Hodgkin photographed an X-ray diffraction pattern of pepsin, Max Perutz started his historic investigation of haemoglobin.[1] Such investigations were, however, thought to be without hope of any success by most of the contemporary crystallographers, who avoided crystals that did not have a short (less than 4.5 Å) axis for projecting resolved atoms. Nevertheless, Perutz computed Patterson functions that suggested haemoglobin contained parallel α-keratin-like bundles of rods (Boyes-Watson *et al.*, 1947; Perutz, 1949). Perutz was correct about the α-keratin-like rods, but not about these being parallel.

In Pasadena, Pauling (Pauling & Corey, 1951; Pauling *et al.*, 1951) was building helical polypeptide models to explain Astbury's α patterns and perhaps to understand the helical structures in globular proteins, such as haemoglobin. Pauling, using his knowledge of the structure of amino acids and peptide bonds, was forced to the conclusion that there need not be an integral number of amino-acid residues per helical turn. He therefore suggested that the 'α-helix', with 3.6 residues per turn, would roughly explain Astbury's α pattern and that his proposed 'β-sheet' structure should be related to Astbury's β pattern. Perutz saw that an α-helical structure should give rise to a strong 1.5 Å-spacing reflection as a consequence of the rise per residue in an α-helix (Perutz, 1951*a*,*b*). Demonstration of this reflection in horse hair, then in fibres of polybenzyl-L-glutamate, in muscle (with Hugh Huxley) and finally in haemoglobin crystals showed that Pauling's proposed α-helix really existed in haemoglobin and presumably also in other globular proteins. Confirmation of helix-like structures came with the observation of cylindrical rods in the 6 Å-resolution structure of myoglobin in 1957 (Kendrew *et al.*, 1958) and eventually at atomic resolution with the 2 Å myoglobin structure in 1959 (Kendrew *et al.*, 1960). The first atomic resolution confirmation of Pauling's β structure did not come until 1966 with the structure determination of hen egg-white lysozyme (Blake, Mair *et al.*, 1967).

Although the stimulus for the Cochran *et al.* (1952) analysis of diffraction from helical structures came from Perutz's studies of helices in polybenzyl-L-glutamate and their presence in haemoglobin, the impact on the structure determination of nucleic acids was even more significant. The events leading to the discovery of the double-helical structure of DNA have been well chronicled (Watson, 1968; Olby, 1974; Judson, 1979). The resultant science, often known exclusively as molecular biology, has created a whole new industry. Furthermore, the molecular-modelling techniques used by Pauling in predicting the structure of α-helices and β-sheets and by Crick and Watson in determining the structure of DNA had a major effect on more traditional crystallography and the structure determinations of fibrous proteins, nucleic acids and polysaccharides.

Another major early result of profound biological significance was the demonstration by Bernal and Fankuchen in the 1930s (Bernal & Fankuchen, 1941) that tobacco mosaic virus (TMV) had a rod-like structure. This was the first occasion where it was possible to obtain a definite idea of the architecture of a virus.

---

[1] Perutz writes, 'I started X-ray work on haemoglobin in October 1937 and Bragg became Cavendish Professor in October 1938. Bernal was my PhD supervisor in 1937, but he had nothing to do with my choice of haemoglobin. I began this work at the suggestion of Haurowitz, the husband of my cousin Gina Perutz, who was then in Prague. The first paper on X-ray diffraction from haemoglobin (and chymotrypsin) was Bernal, Fankuchen & Perutz (Bernal *et al.*, 1938). I did the experimental work, (and) Bernal showed me how to interpret the X-ray pictures.'

Many of the biological properties of TMV had been explored by Wendell Stanley working at the Rockefeller Institute in New York. He had also been able to obtain a large amount of purified virus. Although it was not possible to crystallize this virus, it was possible to obtain a diffraction pattern of the virus in a viscous solution which had been agitated to cause alignment of the virus particles. This led Jim Watson (Watson, 1954) to a simple helical structure of protein subunits. Eventually, after continuing studies by Aaron Klug, Rosalind Franklin, Ken Holmes and others, the structure was determined at atomic resolution (Holmes *et al.*, 1975), in which the helical strand of RNA was protected by the helical array of protein subunits.

1.2.4. Globular proteins in the 1950s

In 1936, Max Perutz had joined Sir Lawrence Bragg in Cambridge. Inspired in part by Keilin (Perutz, 1997), Perutz started to study crystalline haemoglobin. This work was interrupted by World War II, but once the war was over Perutz tenaciously developed a series of highly ingenious techniques. All of these procedures have their counterparts in modern 'protein crystallography', although few today recognize their real origin.

The first of these methods was the use of 'shrinkage' stages (Perutz, 1946; Bragg & Perutz, 1952). It had been noted by Bernal and Crowfoot (Hodgkin) in their study of pepsin that crystals of proteins deteriorate on exposure to air. Perutz examined crystals of horse haemoglobin after they were air-dried for short periods of time and then sealed in capillaries. He found that there were at least seven consecutive discrete shrinkage stages of the unit cell. He realized that each shrinkage stage permitted the sampling of the molecular transform at successive positions, thus permitting him to map the variation of the continuous transform. As he examined only the centric ($h0l$) reflections of the monoclinic crystals, he could observe when the sign changed from 0 to π in the centric projection (Fig. 1.2.4.1). Thus, he was able to determine the phases (signs) of the central part of the ($h0l$) reciprocal lattice. This technique is essentially identical to the use of diffraction data from different unit cells for averaging electron density in the 'modern' molecular replacement method. In the haemoglobin case, Patterson projections had shown that the molecules maintained their orientation relative to the a axis as the crystals shrank, but in the more general molecular replacement case, it is necessary to determine the relative orientations of the molecules in each cell.

The second of Perutz's techniques depended on observing changes in the intensities of low-order reflections when the concentration of the dissolved salts (*e.g.* Cs_2SO_4) in the solution between the crystallized molecules was altered (Boyes-Watson *et al.*, 1947; Perutz, 1954). The differences in structure amplitude, taken together with the previously determined signs, could then map out the parts of the crystal unit cell occupied by the haemoglobin molecule. In many respects, this procedure has its equivalent in 'solvent flattening' used extensively in 'modern' protein crystallography.

The third of Perutz's innovations was the isomorphous replacement method (Green *et al.*, 1954). The origin of the isomorphous replacement method goes back to the beginnings of X-ray crystallography when Bragg compared the diffracted intensities from crystals of NaCl and KCl. J. Monteath Robertson explored the procedure a little further in his studies of phthalocyanines. Perutz used a well known fact that dyes could be diffused into protein crystals, and, hence, heavy-atom compounds might also diffuse into and bind to specific residues in the protein. Nevertheless, the sceptics questioned whether even the heaviest atoms could make a measurable difference to the X-ray diffraction pattern of a protein.[2] Perutz therefore developed an instrument which quantitatively recorded the blackening caused by the reflected X-ray beam on a film. He also showed that the effect of specifically bound atoms could be observed visually on a film record of a diffraction pattern. In 1953, this resulted in a complete sign determination of the ($h0l$) horse haemoglobin structure amplitudes (Green *et al.*, 1954). However, not surprisingly, the projection of the molecule was not very interesting, making it necessary to extend the procedure to noncentric, three-dimensional data. It took another five years to determine the first globular protein structure to near atomic resolution.

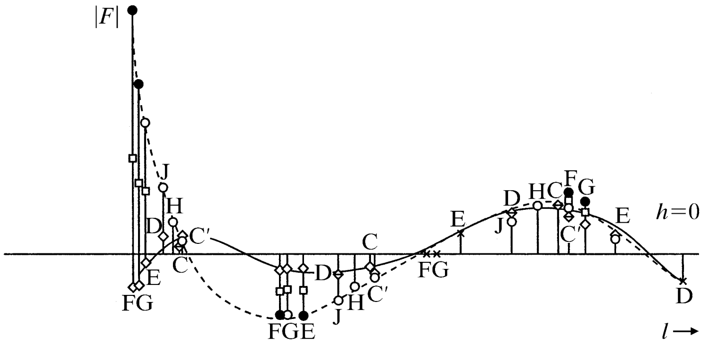

Figure 1.2.4.1
Change of structure amplitude for horse haemoglobin as a function of salt concentration in the suspension medium of the low-order $h0l$ reflections at various lattice shrinkage stages (C, C′, D, E, F, G, H, J). Reprinted with permission from Perutz (1954). Copyright (1954) Royal Society of London.

In 1950, David Harker was awarded one million US dollars to study the structure of proteins. He worked first at the Brooklyn Polytechnic Institute in New York and later at the Roswell Park Cancer Institute in Buffalo, New York. He proposed to solve the structure of proteins on the assumption that they consisted of 'globs' which he could treat as single atoms; therefore, he could solve the structure by using his inequalities (Harker & Kasper, 1947), *i.e.*, by direct methods. He was aware of the need to use three-dimensional data, which meant a full phase determination, rather than the sign determination of two-dimensional projection data on which Perutz had concentrated. Harker therefore decided to develop automatic diffractometers, as opposed to the film methods being used at Cambridge. In 1956, he published a procedure for plotting the isomorphous data of each reflection in a simple graphical manner that allowed an easy determination of its phase (Harker, 1956). Unfortunately, the error associated with the data tended to create a lot of uncertainty.

In the first systematic phase determination of a protein, namely that of myoglobin, phase estimates were made for about 400 reflections. In order to remove subjectivity, independent estimates were made by Kendrew and Bragg by visual inspection of the Harker diagram for each reflection. These were later compared before computing an electron-density map. This process was put onto a more objective basis by calculating phase probabilities, as described by Blow & Crick (1959) and Dickerson *et al.* (1961).

---

[2] Perutz writes, 'I measured the absolute intensity of reflexions from haemoglobin which turned out to be weaker than predicted by Wilson's statistics. This made me realise that about 99% of the scattering contributions of the light atoms are extinguished by interference and that, by contrast, the electrons of a heavy atom, being concentrated at a point, would scatter in phase and therefore make a measurable difference to the structure amplitudes.'

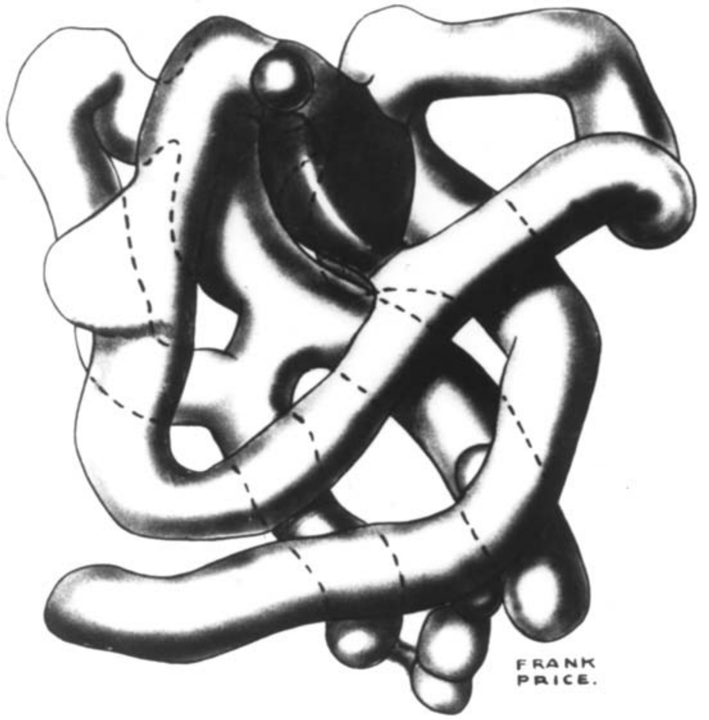

Figure 1.2.5.1
A model of the myoglobin molecule at 6 Å resolution. Reprinted with permission from Bodo *et al.* (1959). Copyright (1959) Royal Society of London.

One problem with the isomorphous replacement method was the determination of accurate parameters that described the heavy-atom replacements. Centric projections were a means of directly determining the coordinates, but no satisfactory method was available to determine the relative positions of atoms in different derivatives when there were no centric projections. In particular, it was necessary to establish the relative y coordinates for the heavy-atom sites in the various derivatives of monoclinic myoglobin and in monoclinic horse haemoglobin. Perutz (1956) and Bragg (1958) had each proposed solutions to this problem, but these were not entirely satisfactory. Consequently, it was necessary to average the results of different methods to determine the 6 Å phases for myoglobin. However, this problem was solved satisfactorily in the structure determination of haemoglobin by using an $(F_{H1} - F_{H2})^2$ Patterson-like synthesis in which the vectors between atoms in the two heavy-atom compounds, H1 and H2, produce negative peaks (Rossmann, 1960). This technique also gave rise to the first least-squares refinement procedure to determine the parameters that define each heavy atom.

Perutz used punched cards to compute the first three-dimensional Patterson map of haemoglobin. This was a tremendous computational undertaking. However, the first digital electronic computers started to appear in the early to mid-1950s. The EDSAC1 and EDSAC2 machines were built in the Mathematical Laboratory of Cambridge University. EDSAC1 was used by John Kendrew for the 6 Å-resolution map of myoglobin (Bluhm *et al.*, 1958). EDSAC2 came online in 1958 and was the computer on which all the calculations were made for the 5.5 Å map of haemoglobin (Cullis *et al.*, 1962) and the 2.0 Å map of myoglobin. It was the tool on which many of the now well established crystallographic techniques were initially developed. By about 1960, the home-built, one-of-a-kind machines were starting to be replaced by commercial machines. Large mainframe IBM computers (704, 709 *etc.*), together with FORTRAN as a symbolic language, became available.

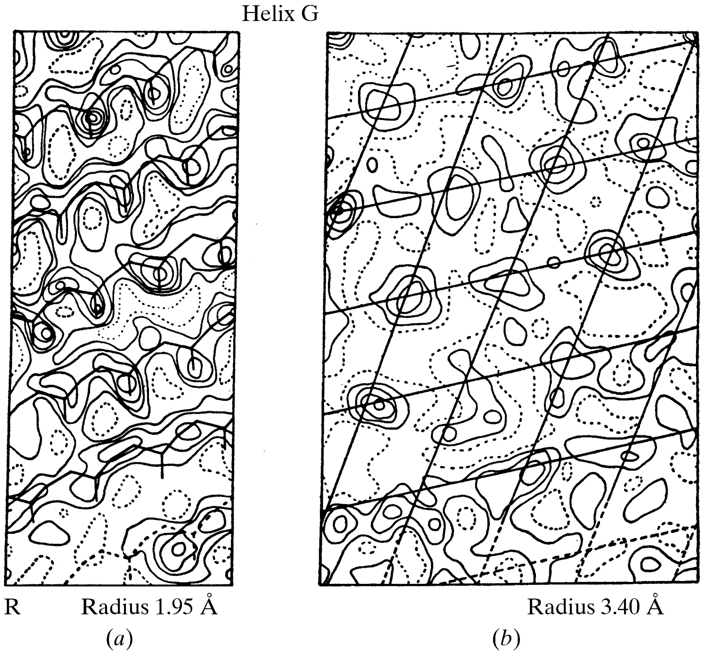

Figure 1.2.5.2
Cylindrical sections through a helical segment of a myoglobin polypeptide chain. (*a*) The density in a cylindrical mantle of 1.95 Å radius, corresponding to the mean radius of the main-chain atoms in an α-helix. The calculated atomic positions of the α-helix are superimposed and roughly correspond to the density peaks. (*b*) The density at the radius of the β-carbon atoms; the positions of the β-carbon atoms calculated for a right-handed α-helix are marked by the superimposed grid (Kendrew & Watson, unpublished). 1.2.5. The first protein structures (1957 to the 1970s)

By the time three-dimensional structures of proteins were being solved, Linderström-Lang (Linderström-Lang & Schellman, 1959) had introduced the concepts of 'primary', 'secondary' and 'tertiary' structures, providing a basis for the interpretation of electron-density maps. The first three-dimensional protein structure to be solved was that of myoglobin at 6 Å resolution (Fig. 1.2.5.1) in 1957 (Kendrew *et al.*, 1958). It clearly showed sausage-like features which were assumed to be α-helices. The iron-containing haem group was identified as a somewhat larger electron-density feature. The structure determination of haemoglobin at 5.5 Å resolution in 1959 (Cullis *et al.*, 1962) showed that each of its two independent chains, α and β, had a fold similar to that of myoglobin and, thus, suggested a divergent evolutionary process for oxygen transport molecules. These first protein structures were mostly helical, features that could be recognized readily at low resolution. Had the first structures been of mostly β structure, as is the case for pepsin or chymotrypsin, history might have been different.

The absolute hand of the haemoglobin structure was determined using anomalous dispersion (Cullis *et al.*, 1962) in a manner similar to that used by Bijvoet. This was confirmed almost immediately when a 2 Å-resolution map of myoglobin was calculated in 1959 (Kendrew *et al.*, 1960). By plotting the electron density of the α-helices on cylindrical sections (Fig. 1.2.5.2), it was possible to see not only that the Pauling prediction of the α-helix structure was accurately obeyed, but also that the C_β atoms were consistent with *laevo* amino acids and that all eight helices were right-handed on account of the steric hindrance that would occur between the C_β atom and carbonyl oxygen in left-handed helices.

The first enzyme structure to be solved was that of lysozyme in 1965 (Blake *et al.*, 1965), following a gap of six years after the excitement caused by the discovery of the globin structures. Diffusion of substrates into crystals of lysozyme showed how substrates bound to the enzyme (Blake, Johnson *et al.*, 1967), which in turn suggested a catalytic mechanism and identified the essential catalytic residues.

From 1965 onwards, the rate of protein-structure determinations gradually increased to about one a year: carboxypeptidase (Reeke *et al.*, 1967), chymotrypsin (Matthews *et al.*, 1967), ribonuclease (Kartha *et al.*, 1967; Wyckoff *et al.*, 1967), papain (Drenth *et al.*, 1968), insulin (Adams *et al.*, 1969), lactate dehydrogenase (Adams *et al.*, 1970) and cytochrome *c* (Dickerson *et al.*, 1971) were early examples. Every new structure was a major event. These structures laid the foundation for structural biology. From a crystallographic point of view, Drenth's structure determination of papain was particularly significant in that he was able to show an amino-acid sequencing error where 13 residues had to be inserted between Phe28 and Arg31, and he showed that a 38-residue peptide that had been assigned to position 138 to 176 needed to be transposed to a position between the extra 13 residues and Arg31.

The structures of the globins had suggested that proteins with similar functions were likely to have evolved from a common precursor and, hence, that there might be a limited number of protein-folding motifs. Comparison of the active centres of chymotrypsin and subtilisin showed that convergent evolutionary pathways could exist (Drenth *et al.*, 1972; Kraut *et al.*, 1972).

The variety of structures that were being studied increased rapidly. The first tRNA structures were determined in the 1960s (Kim *et al.*, 1973; Robertus *et al.*, 1974), the first spherical virus structure was published in 1978 (Harrison *et al.*, 1978) and the photoreaction centre membrane protein structure appeared in 1985 (Deisenhofer *et al.*, 1985). The rate of new structure determinations has continued to increase exponentially. In 1996, about one new structure was published every day. Partly in anticipation and partly to assure the availability of results, the Brookhaven Protein Data Bank (PDB) was brought to life at the 1971 Cold Spring Harbor Meeting (H. Berman & J. L. Sussman, private communication). Initially, it was difficult to persuade authors to submit their coordinates, but gradually this situation changed to one where most journals require coordinate submission to the PDB, resulting in today's access to structural results *via* the World Wide Web.

The growth of structural information permitted generalizations, such as that β-sheets have a left-handed twist when going from one strand to the next (Chothia, 1973) and that 'cross-over' β-α-β turns were almost invariably right-handed (Richardson, 1977). These observations and the growth of the PDB have opened up a new field of science. Among the many important results that have emerged from this wealth of data is a careful measurement of the main-chain dihedral angles, confirming the predictions of Ramachandran (Ramachandran & Sasisekharan, 1968), and of side-chain rotamers (Ponder & Richards, 1987). Furthermore, it is now possible to determine whether the folds of domains in a new structure relate to any previous results quite conveniently (Murzin *et al.*, 1995; Holm & Sander, 1997).

1.2.6. Technological developments (1958 to the 1980s)

In the early 1960s, there were very few who had experience in solving a protein structure. Thus, almost a decade passed after the success with the globins before there was a noticeable surge of new structure reports. In the meantime, there were persistent attempts to find alternative methods to determine protein structure.

Blow & Rossmann (1961) demonstrated the power of the single isomorphous replacement method. While previously it had been thought that it was necessary to have at least two heavy-atom compounds, if not many more, they showed that a good representation of the structure of haemoglobin could have been made by using only one good derivative. There were also early attempts at exploiting anomalous dispersion for phase determination. Rossmann (1961) showed that anomalous differences could be used to calculate a 'Bijvoet Patterson' from which the sites of the anomalous scatterers (and, hence, heavy-atom sites) could be determined. Blow & Rossmann (1961), North (1965) and Matthews (1966) used anomalous-dispersion data to help in phase determination. Hendrickson stimulated further interest by using Cu $K\alpha$ radiation and employing the anomalous effect of sulfur atoms in cysteines to solve the entire structure of the crambin molecule (Hendrickson & Teeter, 1981). With today's availability of synchrotrons, and hence the ability to tune to absorption edges, these early attempts to utilize anomalous data have been vastly extended to the powerful multiple-wavelength anomalous dispersion (MAD) method (Hendrickson, 1991). More recently, the generality of the MAD technique has been greatly expanded by using proteins in which methionine residues have been replaced by selenomethionine, thus introducing selenium atoms as anomalous scatterers.

Another advance was the introduction of the 'molecular replacement' technique (Rossmann, 1972). The inspiration for this method arose out of the observation that many larger proteins (*e.g.* haemoglobin) are oligomers of identical subunits and that many proteins can crystallize in numerous different forms. Rossmann & Blow (1962) recognized that an obvious application of the technique would be to viruses with their icosahedral symmetry. They pointed out that the symmetry of the biological oligomer can often be, and sometimes must be, 'noncrystallographic' or 'local', as opposed to being true for the whole infinite crystal lattice. Although the conservation of folds had become apparent in the study of the globins and a little later in the study of dehydrogenases (Rossmann *et al.*, 1974), in the 1960s the early development of the molecular replacement technique was aimed primarily at *ab initio* phase determination (Rossmann & Blow, 1963; Main & Rossmann, 1966; Crowther, 1969). It was only in the 1970s, when more structures became available, that it was possible to use the technique to solve homologous structures with suitable search models. Initially, there was a good deal of resistance to the use of the molecular replacement technique. Results from the rotation function were often treated with scepticism, the translation problem was thought to have no definitive answer, and there were excellent reasons to consider that phasing was impossible except for centric reflections (Rossmann, 1972). It took 25 years before the full power of all aspects of the molecular replacement technique was fully utilized and accepted (Rossmann *et al.*, 1985).

The first real success of the rotation function was in finding the rotational relationship between the two independent insulin monomers in the *P*3 unit cell (Dodson *et al.*, 1966). Crowther produced the fast rotation function, which reduced the computational times to manageable proportions (Crowther, 1972). Crowther (1969) and Main & Rossmann (1966) were able to formulate the problem of phasing in the presence of noncrystallographic symmetry in terms of a simple set of simultaneous

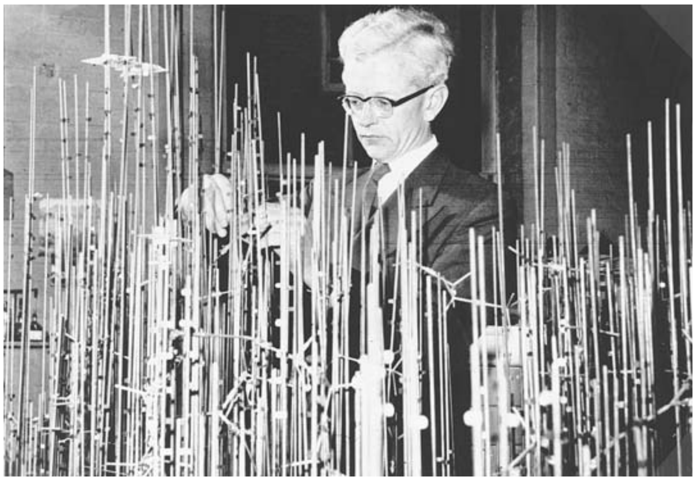

Figure 1.2.6.1
The 2 Å-resolution map of sperm-whale myoglobin was represented by coloured Meccano-set clips on a forest of vertical rods. Each clip was at a grid point. The colour of the clip indicated the height of the electron density. The density was interpreted in terms of 'Corey–Pauling' models on a scale of 5 cm = 1 Å. Pictured is John Kendrew. (This figure was provided by M. F. Perutz.)

complex equations. However, real advances came with applying the conditions of noncrystallographic symmetry in real space, which was the key to the solution of glyceraldehyde-3-phosphate dehydrogenase (Buehner *et al.*, 1974), tobacco mosaic virus disk protein (Bloomer *et al.*, 1978) and other structures, aided by Gerard Bricogne's program for electron-density averaging (Bricogne, 1976), which became a standard of excellence.

No account of the early history of protein crystallography is complete without a mention of ways of representing electron density. The 2 Å map of myoglobin was interpreted by building a model (on a scale of 5 cm to 1 Å with parts designed by Corey and Pauling at the California Institute of Technology) into a forest of vertical rods decorated with coloured clips at each grid point, representing the height of the electron density (Fig. 1.2.6.1). Later structures, such as those of lysozyme and carboxypeptidase, were built with 'Kendrew' models (2 cm to 1 Å) based on electron-density maps displayed as stacks of large Plexiglas sheets. A major advance came with Fred Richards' invention of the optical comparator (a 'Richards box' or 'Fred's folly') in which the model was optically superimposed onto the electron density by reflection of the model in a half-silvered mirror (Richards, 1968). This allowed for convenient fitting of model parts and accurate placement of atoms within the electron density. The Richards box was the forerunner of today's computer graphics, originally referred to as an 'electronic Richards box'. The development of computer graphics for model building was initially met with reservation, but fortunately those involved in these developments persevered. Various programs became available for model building in a computer, but the undoubted champion of this technology was *FRODO*, written by Alwyn Jones (Jones, 1978).

1.2.7. Meetings

The birth of protein crystallography in the 1950s coincided with the start of the jet age, making attendance at international meetings far easier. Indeed, the number and variety of meetings have proliferated as much as the number and variety of structures determined. A critical first for protein crystallography was a meeting held at the Hirschegg ski resort in Austria in 1966. This was organized by Max Perutz (Cambridge) and Walter Hoppe (München). About 40 scientists from around the world attended, as well as a strong representation of students (including Robert Huber) from the Münich laboratory. The first Hirschegg meeting occurred just after the structure determination of lysozyme, which helped lift the cloud of pessimism after the long wait for a new structure since the structures of the globins had been solved in the 1950s. The meeting was very much a family affair where most attendees stayed an extra few days for additional skiing. The times were more relaxed in comparison with those of today's jet-setting scientists flying directly from synchrotron to international meeting, making ever more numerous important discoveries. A second Hirschegg meeting occurred two years later, but this time the number of participants had doubled. By 1970, the meeting had to be transferred to the village of Alpbach, which had more accommodation; however, most of the participants still knew each other.

Another set of international meetings (or schools, as the Italians preferred to call them) was initiated by the Italian crystallographers in 1976 at Erice, a medieval hilltop town in Sicily. These meetings have since been repeated every six years. The local organizer was Lodovico Riva di Sanseverino, whose vivacious sensitivity instilled a feeling of international fellowship into the rapidly growing number of structural biologists. The first meeting lasted two whole weeks, a length of time that would no longer be acceptable in today's hectic, competitive atmosphere.

It took time for the staid organizers of the IUCr triennial congress to recognize the significance of macromolecular structure. Thus, for many years, the IUCr meetings were poorly attended by structural biologists. However, recent meetings have changed, with biological topics representing about half of all activities. Nevertheless, the size of these meetings and their lack of focus have led to numerous large and small specialized meetings, from small Gordon Conferences and East and West Coast crystallography meetings in the USA to huge international congresses in virology, biochemistry and other sciences.

The publication of this volume by the International Union of Crystallography, the first volume of *International Tables* devoted to macromolecular crystallography, strongly attests to the increasing importance of this vital area of science.

I am gratefully indebted to Sharon Wilder, who has done much of the background checking that was required to write this chapter. Furthermore, she has been my permanent and faithful helper during a time that is, in part, covered in the review. I am additionally indebted to Max Perutz and David Davies, both of whom read the manuscript very carefully, making it possible to add a few personal accounts. I also thank the National Institutes of Health and the National Science Foundation for generous financial support.

Chapter 1.3. Macromolecular crystallography and medicine

W. G. J. Hol and C. L. M. J. Verlinde

1.3.1. Introduction

In the last hundred years, crystallography has contributed immensely to the expansion of our understanding of the atomic structure of matter as it extends into the three spatial dimensions in which we describe the world around us. At the beginning of this century, the first atomic arrangements in salts, minerals and low-molecular-weight organic and metallo-organic compounds were unravelled. Then, initially one by one, but presently as an avalanche, the molecules of life were revealed in full glory at the atomic level with often astonishing accuracy, beginning in the 1950s when fibre diffraction first helped to resolve the structure of DNA, later the structures of polysaccharides, fibrous proteins, muscle and filamentous viruses. Subsequently, single-crystal methods became predominant and structures solved in the 1960s included myoglobin, haemoglobin and lysozyme, all of which were heroic achievements by teams of scientists, often building their own X-ray instruments, pioneering computational methods, and improving protein purification and crystallization procedures. Quite soon thereafter, in 1978, the three-dimensional structures of the first viruses were determined at atomic resolution. Less than ten years later, the mechanisms and structures of membrane proteins started to be unravelled. Presently, somewhere between five and ten structures of proteins are solved each day, about 85% by crystallographic procedures and about 15% by NMR methods. It is quite possible that within a decade the Protein Data Bank (PDB; Bernstein *et al.*, 1977) will receive a new coordinate set for a protein, RNA or DNA crystal structure every half hour. The resolution of protein crystal structures is improving dramatically and the size of the structures tackled is sometimes enormous: a virus with over a thousand subunits has been solved at atomic resolution (Grimes *et al.*, 1995) and the structure of the ribosome is on its way (Ban *et al.*, 1999; Cate *et al.*, 1999; Clemons *et al.*, 1999).

Macromolecular crystallography, discussed here in terms of its impact on medicine, is clearly making immense strides owing to a synergism of progress in many scientific disciplines including:

(*a*) *Computer hardware and software*: providing unprecedented computer power as well as instant access to information anywhere on the planet *via* the internet.

(*b*) *Physics*: making synchrotron radiation available with a wide range of wavelengths, very narrow bandwidths and very high intensities.

(*c*) *Materials science and instrumentation*: revolutionizing X-ray intensity measurements, with currently available charge-coupled-device detectors allowing protein-data collection at synchrotrons in tens of minutes, and with pixel array detectors on the horizon which are expected to collect a complete data set from a typical protein within a few seconds.

(*d*) *Molecular biology*: allowing the cloning, overexpression and modification of genes, with almost miraculous ease in many cases, resulting in a wide variety of protein variants, thereby enabling crystallization of 'impossible' proteins.

(*e*) *Genome sequencing*: determining complete bacterial genomes in a matter of months. With several eukaryote genomes and the first animal genome already completed, and with the human genome expected to be completed to a considerable degree by 2000, protein crystallographers suddenly have an unprecedented choice of proteins to study, giving rise to the new field of structural genomics.

(*f*) *Biochemistry and biophysics*: providing a range of tools for rapid protein and nucleic acid purification by size, charge and affinity, and for characterization of samples by microsequencing, fluorescence, mass spectrometry, circular dichroism and dynamic light scattering procedures.

(*g*) *Chemistry, in particular combinatorial chemistry*: discovering by more and more sophisticated procedures high affinity inhibitors or binders to drug target proteins which are of great interest by themselves, while in addition such compounds tend to improve co-crystallization results quite significantly.

(*h*) *Crystallography itself*: constantly developing new tools including direct methods, multi-wavelength anomalous-dispersion phasing techniques, maximum-likelihood procedures in phase calculation and coordinate refinement, interactive graphics and automatic model-building programs, density-modification methods, and the extremely important cryo-cooling techniques for protein and nucleic acid crystals, to mention only some of the major achievements in the last decade.

Numerous aspects of these developments are treated in great detail in this volume of *International Tables.*

1.3.2. Crystallography and medicine

Knowledge of accurate atomic structures of small molecules, such as vitamin B_{12}, steroids, folates and many others, has assisted medicinal chemists in their endeavours to modify many of these molecules for the combat of disease. The early protein crystallographers were well aware of the potential medical implication of the proteins they studied. Examples are the studies of the oxygen-carrying haemoglobin, the messenger insulin, the defending antibodies and the bacterial-cell-wall-lysing lysozyme. Yet, even by the mid-1980s, there were very few crystallographic projects which had the explicit goal of arriving at pharmaceutically active compounds (Hol, 1986). Since then, however, we have witnessed an incredible increase in the number of projects in this area with essentially every major pharmaceutical company having a protein crystallography unit, while in academia and research institutions the potential usefulness of a protein structure is often combined with the novelty of the system under investigation. In one case, the HIV protease, it might well be that, worldwide, the structure has been solved over one thousand times – in complex with hundreds of different inhibitory compounds (Vondrasek *et al.*, 1997).

Impressive as these achievements are, this seems to be only the beginning of medicinal macromolecular crystallography. The completion of the human genome project will provide an irresistible impetus for '*human structural genomics*': the determination, as rapidly and systematically as possible, of as many human protein structures as possible. The genome sequences of most

Table 1.3.3.1
Crystal structures and genetic diseases

Crystal structure	Disease	Reference
Acidic fibroblast growth factor receptor	Familial Pfeiffer syndrome	[1]
Alpha-1-antitrypsin	Alpha-1-antitrypsin deficiency	[2]
Antithrombin III	Hereditary thrombophilia	[3], [4]
Arylsulfatase A	Leukodystrophy	[5]
Aspartylglucosaminidase	Aspartylglusominuria	[6]
Beta-glucuronidase	Sly syndrome	[7]
Branched-chain alpha-keto acid dehydrogenase	Maple syrup urine syndrome, type Ia	[39]
Carbonic anhydrase II	Guibaud–Vainsel syndrome, Marble brain disease	[8]
p53	Cancer	[9], [10]
Ceruloplasmin	Hypoceruloplasminemia	[11]
Complement C3	C3 complement component 3 deficiency	[12]
Cystatin B	Progressive myoclonus epilepsy	[13]
Factor VII	Factor VII deficiency	[14]
Factor VIII	Factor VIII deficiency	[40]
Factor X	Factor X deficiency (Stuart–Prower factor deficiency)	[15]
Factor XIII	Factor XIII deficiency	[16]
Fructose-1,6-bisphosphate aldolase	Fructose intolerance (fructosemia)	[41]
Gelsolin	Amyloidosis V	[17]
Growth hormone	Growth hormone deficiency	[18]
Haemochromatosis protein HFE	Hereditary haemochromatosis	[19]
Haemoglobin	Beta-thalassemia, sickle-cell anaemia	[20]
Tyrosine hydroxylase	Hereditary Parkinsonism	[21]
Hypoxanthine–guanine phosphoribosyltransferase	Lesch–Nyhan syndrome	[22]
Insulin	Hyperproinsulinemia, diabetes	[42]
Isovaleryl–coenzyme A dehydrogenase	Isovaleric acid CoA dehydrogenase deficiency	[23]
Lysosomal protective protein	Galactosialidosis	[24]
Ornithine aminotransferase	Ornithine aminotransferase deficiency	[25]
Ornithine transcarbamoylase	Ornithine transcarbamoylase deficiency	[43]
p16INK4a tumour suppressor	Cancer	[26]
Phenylalanine hydroxylase	Phenylketonuria	[27]
Plasminogen	Plasminogen deficiency	[28], [29], [30]
Protein C	Protein C deficiency	[31]
Purine nucleotide phosphorylase	Purine nucleotide phosphorylase deficiency	[32]
Serum albumin	Dysalbuminemic hyperthyroxinemia	[33]
Superoxide dismutase (Cu, Zn-dependent)	Familial amyotrophical lateral sclerosis	[34]
Thrombin	Hypoprothrombinemia, dysprothrombinemia	[35]
Transthyretrin	Amyloidosis I	[36]
Triosephosphate isomerase	Triosephosphate isomerase deficiency	[37]
Trypsinogen	Hereditary pancreatitis	[38]

major infectious agents will be completed five years hence, if not sooner. This is likely to be followed up by '*selected pathogen structural genomics*', which will provide a wealth of pathogen protein structures for the design of new pharmaceuticals and probably also for vaccines.

This overview, written in late 1999, aims to convey some feel of the current explosion of 'crystallography in medicine'. Ten, perhaps even five, years ago it might have been feasible to make an almost comprehensive list of all protein structures of potentially direct medical relevance. Today, this is virtually impossible. Here we mention only selected examples in the text with apologies to the crystallographers whose projects should also have been mentioned, and to the NMR spectroscopists and electron microscopists whose work falls outside the scope of this review. Tables 1.3.3.1 and 1.3.4.1 to 1.3.4.5 provide more information, yet do not claim to cover comprehensively this exploding field. Also, not all of the structures listed were determined with medical applications in mind, though they might be exploited for drug design one day. These tables show at the same time tremendous achievements as well as great gaps in our structural knowledge of proteins from humans and human pathogens.

1.3.3. Crystallography and genetic diseases

Presently, an immense number of genetic diseases have been characterized at the genetic level and archived in OMIM [On-line Mendelian Inheritance in Man. Center for Medical Genetics, Johns Hopkins University (Baltimore, MD) and the National Center for Biotechnology Information, National Library of Medicine (Bethesda, MD), 1999. URL: http://www.ncbi.nlm.nih.gov/omim/], with many more discoveries to occur in the next decades. Biomolecular crystallography has been very successful in explaining the cause of numerous genetic diseases at the atomic level. The stories of sickle cell anaemia, thalassemias and other deficiencies of haemoglobin set the stage (Dickerson & Geis, 1983), followed by numerous other examples (Table 1.3.3.1). Given the frequent occurrence of mutations in humans, it is likely that for virtually every structure of a human protein, a number of genetic diseases can be rationalized at the atomic level. Two investigations from the authors' laboratory may serve as examples:

(i) The severity of various cases of galactosialidosis – a lysosomal storage disease – could be related to the predicted effects of the amino-acid substitutions on the stability of human protective protein cathepsin A (Rudenko *et al.*, 1998).

(ii) The modification of Tyr393α to Asn in the branched-chain 2-oxo acid dehydrogenase occurs at the interface of the α and β subunits in this $\alpha_2\beta_2$ heterotetramer, providing a nice explanation of the 'mennonite' variants of maple syrup urine disease (MSUD) (Ævarsson *et al.*, 2000).

Impressive as the insights obtained into the causes of diseases like these might be, there is almost a sense of tragedy associated with this detailed understanding of a serious, sometimes fatal, afflictions at the atomic and three-dimensional level: there is often so little one can *do* with this knowledge. There are at least two, very different, reasons for this. The first reason is that turning a malfunctioning protein or nucleic acid into one that functions properly is notoriously difficult. Treatment would generally require the oral use of small molecules that somehow counteract the effect of the mutation, *i.e. the administration of the small molecule has to result in a functional complex of the drug with the mutant protein*. This is in almost all cases far more difficult than finding compounds that *block* the activity of a protein or nucleic acid – which is the way in which most current drugs function. The second reason for the paucity of drugs for treating genetic diseases is very different in nature: the number of patients suffering from a particular mutation responsible for a genetic disease is very small in most cases. This means that market forces do not encourage funding the expensive steps of testing the toxicity and efficacy of potentially pharmaceutically active compounds. One of several exceptions is sickle cell anaemia, where significant efforts have been made to arrive at pharmaceutically active agents (Rolan *et al.*, 1993). In this case the mutation Glu6βVal leads to deoxyhaemoglobin polymerization *via* the hydrophobic valine. In spite of several ingenious approaches based on the allosteric properties of haemoglobin (Wireko & Abraham, 1991), no successful compound seems to be on the horizon yet for the treatment of sickle cell anaemia.

More recently, the spectacular molecular mechanisms underlying genetic serpin deficiency diseases have been elucidated. A typical example is α1-antitrypsin deficiency, which leads to cirrhosis and emphysema. Normal α1-antitrypsin, a serine protease inhibitor, exposes a peptide loop as a substrate for the cognate proteinase in its active but metastable conformation. After cleavage of the loop, the protease becomes trapped as an acyl-enzyme with the serpin, and the cleaved serpin loop inserts itself as the central strand of one of the serpin β-sheets, accompanied by a dramatic change in protein stability. In certain mutant serpins, however, the exposed loop is conformationally more metastable and occasionally inserts itself into the β-sheet of a neighbouring serpin molecule, thereby forming serpin polymers with disastrous consequences for the patient (Carrell & Gooptu, 1998). *In vitro*, the polymerization of α1-antitrypsin can be reversed with synthetic homologues of the exposed peptide loop (Skinner *et al.*, 1998). This approach might be useful for other 'conformational diseases', which include Alzheimer's and other neurodegenerative disorders.

Another frequently occurring genetic disease is cystic fibrosis. Here we face a more complex situation than that in the case of sickle cell anaemia: a range of different mutations causes a malfunctioning of the same ion channel, which, consequently, leads to a range of severity of the disease (Collins, 1992). Protein crystallography is currently helpful in an indirect way in alleviating the problems of cystic fibrosis patients, not by studying the affected ion channel itself, but by revealing the structure of leukocyte elastase (Bode *et al.*, 1986), an enzyme responsible for much of the cellular damage associated with cystic fibrosis (Birrer, 1995). On the basis of the elastase structure, inhibitors were developed to combat the effects of the impaired ion channel (Warner *et al.*, 1994). Also, structures of key enzymes of *Pseudomonas aeruginosa*, a bacterium affecting many cystic fibrosis patients, form a basis for the design of therapeutics to treat infections by this pathogen. Yet, to the best of our knowledge, no compound has been developed so far that repairs the malfunctioning ion channel.

However, in some cases there might be more opportunities than assumed so far. Several mutations leading to genetic diseases result in a lack of stability of the affected protein. In instances when the mutant protein is still stable enough to fold, small molecules could conceivably be discovered that bind 'anywhere' to a pocket of these proteins, thereby stabilizing the protein. The same small molecule could even be able to increase the stability of proteins with *different* mildly destabilizing mutations. Such an approach, though not trivial by any means, might be worth pursuing. Proof of principle of this concept has recently been provided for several unstable p53 mutants, where the *same* small molecule enhanced the stability of *different* mutants (Foster *et al.*, 1999).

Of course, mutations that destroy cofactor binding or active sites, or destroy proper recognition of partner proteins, will be extremely difficult to correct by small molecules targeting the affected protein. In such instances, gene therapy is likely to be the way by which our and the next generation may be able to improve the lives of future generations.

1.3.4. Crystallography and development of novel pharmaceuticals

The impact of detailed knowledge of protein and nucleic acid structures on the design of new drugs has already been significant, and promises to be of tremendous importance in the next decades. The first structure of a known major drug bound to a target protein was probably that of methotrexate bound to dihydrofolate reductase (DHFR) (Matthews *et al.*, 1977). Even though the source of the enzyme was bacterial while methotrexate is used as a human anticancer agent, this protein–drug complex structure was nevertheless a hallmark achievement. It is generally accepted that the first protein-structure-inspired drug actually reaching the market was captopril, which is an antihypertensive compound blocking the action of angiotensin-converting enzyme, a metalloprotease. In this case, the structure of zinc-containing carboxypeptidase A was a guide to certain aspects of the chemical modification of lead compounds (Cushman & Ondetti, 1991). This success has been followed up by numerous projects specifically aimed at the design of new inhibitors, or activators, of carefully selected drug targets.

Structure-based drug design (SBDD) (Fig. 1.3.4.1) is the subject of several books and reviews that summarize projects and several success stories up until the mid-1990s (Kuntz, 1992; Perutz, 1992; Verlinde & Hol, 1994; Whittle & Blundell, 1994; Charifson, 1997; Veerapandian, 1997). Possibly the most dramatic impact made by SBDD has been on the treatment of AIDS, where the development of essentially all of the protease inhibitors on the market in 1999 has been guided by, or at least assisted by, the availability of numerous crystal structures of protease–inhibitor complexes.

The need for a large number of structures is common in all drug design projects and is due to several factors. One is the tremendous challenge for theoretical predictions of the correct binding mode and affinity of inhibitors to proteins. The current force fields are approximate, the properties of water are treacherous, the flexibility of protein and ligands lead quickly to a combinatorial explosion, and the free-energy differences between various binding modes are small. All this leads to the need for several experimental structures in a structure-based drug design cycle (Fig. 1.3.4.1). In this cycle, numerous disciplines are interacting in multiple ways. Many institutions, small and large, are following in one way or another this paradigm to speed up the lead discovery, lead optimization and even the bioavailability improvement steps in the drug development process. Moreover, a very powerful synergism exists between combinatorial chemistry and structure-based drug design. Structure-guided combinatorial libraries can utilize knowledge of ligand target sites in the design of the library [see *e.g.* Ferrer *et al.* (1999), Eckert *et al.* (1999) and Minke *et al.* (1999)]. Once tight-binding ligands are found by combinatorial methods, crystal structures of library compound–target complexes provide detailed information for new highly specific libraries.

The fate of a drug candidate during clinical tests can hinge on a single methyl group – just as a point mutation can alter the benefit of a wild-type protein molecule into the nightmare of a life-long genetic disease. Hence, many promising inhibitors eventually fail to be of benefit to patients. Nevertheless, knowledge of a *series* of protein structures in complex with inhibitors is of immense value in the design and development of future pharmaceuticals. In the following sections some examples will be looked at.

1.3.4.1. *Infectious diseases*

1.3.4.1.1. *Viral diseases*

Some icosahedral pathogenic viruses have all their capsid proteins elucidated, while for the more complex viruses like influenza virus, hepatitis C virus (HCV) and HIV, numerous individual protein structures have been solved (Table 1.3.4.1). However, not all 14 native proteins of the HIV genome have yet surrendered to the crystallographic community, nor to the NMR spectroscopists or the high-resolution electron microscopists, our partners in experimental structural biology (Turner & Summers, 1999). Nevertheless, the structures of HIV protease, reverse transcriptase and fragments of HIV integrase and of HIV viral core and surface proteins are of tremendous value for developing novel anti-AIDS therapeutics [Arnold *et al.*, 1996; Lin *et al.*, 1998; Wlodawer & Vondrasek, 1998; see also references in Table 1.3.4.1(*a*)]. A similar situation occurs for hepatitis C virus. The protease structure of this virus has been solved recently (simultaneously by four groups!), as well as its helicase structure, providing platforms on the basis of which the design of novel drugs is actively pursued (Le *et al.*, 1998).

A quite spectacular example of how structural knowledge can lead to the synthesis of powerful inhibitors is provided by influenza virus neuraminidase. The structure of a neuraminidase–transition-state analogue complex suggested the addition of positively charged amino and guanidinium groups to the C4 position of the analogue, which resulted, in one step, in a gain of four orders of magnitude in binding affinity for the target enzyme (von Itzstein *et al.*, 1993).

1.3.4.1.2. *Bacterial diseases*

A very large number of structures of important drug target proteins of bacterial origin have been solved crystallographically (Table 1.3.4.2). Currently, the most important single infectious bacterial agent is *Mycobacterium tuberculosis*, with three million deaths and eight million new cases annually (Murray & Salomon, 1998). The crystal structures of several *M. tuberculosis* potential and proven drug target proteins have been elucidated (Table 1.3.4.2). The complete *M. tuberculosis* genome has been sequenced recently (Cole *et al.*, 1998), and this will undoubtedly have a tremendous impact on future drug development.

The crystal structures of many bacterial dihydrofolate reductases, the target of several antimicrobials including trimethoprim, have also been reported. Recently, the atomic structure of dihydropteroate synthase (DHPS), the target of sulfa drugs, has been elucidated, almost 60 years after the first sulfa drugs were used to treat patients (Achari *et al.*, 1997; Hampele *et al.*, 1997).

A very special set of bacterial proteins are the toxins. Some of these have dramatic effects, with even a single molecule able to kill a host cell. These toxins outsmart and (mis)use many of the defence systems of the host, and their structures are often most unusual and fascinating, as recently reviewed by Lacy & Stevens (1998). The structures of the toxins are actively used for the design of prophylactics and therapeutic agents to treat bacterial diseases [see *e.g.* Merritt *et al.* (1997), Kitov *et al.* (2000) and Fan *et al.* (2000)]. It is remarkable that the properties of these devastating toxins are also used, or at least considered, for the treatment of disease, such as in the engineering of diphtheria toxin to create immunotoxins for the treatment of cancer and the deployment of cholera toxin mutants as adjuvants in mucosal vaccines. Knowledge of the three-dimensional structures of these toxins assists in the design of new therapeutically useful proteins.

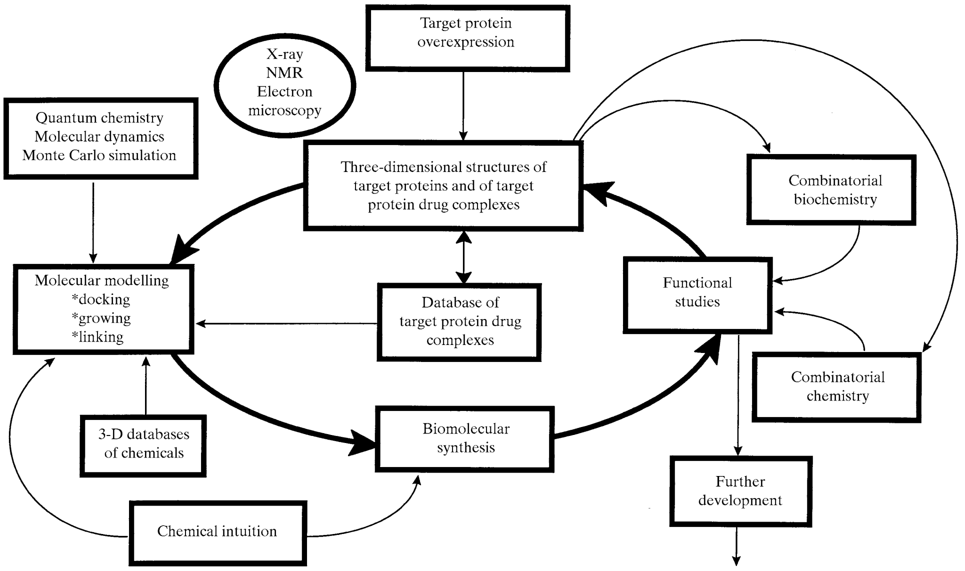

Figure 1.3.4.1
The structure-based drug design cycle.

1.3.4.1.3. *Protozoan infections*

A major cause of death and worldwide suffering is due to infections by several protozoa, including:

Table 1.3.4.1
Important human pathogenic viruses and their proteins

(*a*) RNA viruses
(i) Single-stranded

Family	Example	Protein structures solved	Reference
Arenaviridae	Lassa fever virus	None	
Bunyaviridae	Hantavirus	None	
Caliciviridae	Hepatitis E virus, Norwalk virus	None

Rhabdovirus	Rabies virus	None	
Togaviridae	Rubella	None	

(ii) Double-stranded

Family	Example	Protein structures solved	Reference
Reoviridae	Rotavirus	None	

(*b*) DNA viruses
(i) Single-stranded

Family	Example	Protein structures solved	Reference
Parvoviridae	B 19 virus	None	

(*a*) *Plasmodium falciparum* and related species, causing various forms of malaria;
(*b*) *Trypanosoma cruzi*, the causative agent of Chagas' disease in Latin America;
(*c*) *Trypanosoma brucei*, causing sleeping sickness in Africa;
(*d*) Some eleven different *Leishmania* species, responsible for several of the most horribly disfiguring diseases known to mankind.

Drug resistance, combined with other factors, has been the cause of a major disappointment for the early hopes of a 'malaria eradication campaign'. Fortunately, new initiatives have been launched recently under the umbrella of the 'Malaria roll back' program and the 'Multilateral Initiative for Malaria' (MIM). We are facing a formidable challenge, however, since the parasite is very clever at evading the immune response of the human host. Drugs are the mainstay of current treatments and may well be so for a long time to come. Protein crystallographic studies of *Plasmodium* proteins are hampered by the unusual codon usage of the *Plasmodium* species, coupled with a tendency to contain insertions of numerous hydrophilic residues in the polypeptide chain (Gardner *et al.*, 1998) which provide sometimes serious obstacles to obtaining large amounts of *Plasmodium* proteins for structural investigations.

However, the structures of an increasing number of potential drug targets from these protozoan parasites are being unravelled. These include the variable surface glycoproteins (VSGs) and glycolytic enzymes of *Trypanosoma brucei*, crucial malaria proteases, and the remarkable trypanothione reductase (Table 1.3.4.3). The structures of nucleotide phosphoribosyl transferases of a variety of protozoan parasites have also been elucidated. Moreover, the structure of DHFR from *Pneumocystis carinii*, the major opportunistic pathogen in AIDS patients in the United States, has been determined. Several of these structures are serving as starting points for the development of new drugs.

1.3.4.1.4. Fungi

In general, the human immune system is able to keep the growth of fungi under control, but in immuno-compromised

Table 1.3.4.1 (continued)

(ii) Double-stranded

Family	Example	Protein structures solved	Reference
Adenoviridae	Adenovirus	Protease	[28]
		Capsid	[29]
		Knob domain of fibre protein	[30]
Hepadnaviridae	Hepatitis B	Capsid	[31]
Herpesviridae	Cytomegalovirus	Protease	[32], [33], [34]
	Epstein–Barr virus	Domains of nuclear antigen 1	[35]
		BCRF1	[36]
	Herpes simplex	Protease	[37]
		Thymidine kinase	[38]
		Uracyl-DNA glycosylase	[39]
		Core of VP16	[40]
	Varicella zoster	Protease	[42]
Papovaviridae	Papillomavirus	DNA-binding domain of E2	[43]
		Activation domain of E2	[44]
Poxviridae	Smallpox virus	None	
	Vaccinia virus (related to smallpox but non-pathogenic)	Methyltransferase VP39	[45]
		Domain of topoisomerase	[46]

patients (*e.g.* as a result of cancer chemotherapy, HIV infection, transplantation patients receiving immunosuppressive drugs, genetic disorders) such organisms are given opportunities they usually do not have. *Candida albicans* is an opportunistic fungal organism which causes serious complications in immunocompromised patients. Several of its proteins have been structurally characterized (Table 1.3.4.3) and provide opportunities for the development of selectively active inhibitors.

1.3.4.1.5. *Helminths*

Worms affect the lives of billions of human beings, causing serious morbidity in many ways. *Onchocerca volvolus* is the cause of river blindness, which resulted in the virtual disappearance of entire villages in West Africa, until ivermectin appeared. This remarkable compound dramatically reduced the incidence of the disease, even though it does not kill the adult worms. Therefore, a biological clock is ticking, waiting until resistance occurs against this single compound available for treatment. *Schistosoma* species are responsible for a wide variety of liver diseases and are spreading continuously since irrigation schemes provide a perfect environment for the intermediate snail vector. Other medically important helminths are *Wuchereria bancrofti* and *Brugia malayi.* Only a few protein structures from these very important disease-causing organisms have been unravelled so far (Table 1.3.4.3).

1.3.4.2. *Resistance*

Resistance to drugs in infectious organisms, as well as in cancers, is a fascinating subject, since it demonstrates the action and reaction of biological systems in response to environmental challenges. Life, of course, has been evolving to do just that – and the arrival of new chemicals, termed ‘drugs’, on the scene is nothing new to organisms that are the result of evolutionary processes involving billions of years of chemical warfare. Populations of organisms span a wide range of variation at the genetic and protein levels, and the chance that one of the variants is able to cope with drug pressure is nonzero. The variety of mechanisms observed to be responsible for drug resistance is impressive (Table 1.3.4.4).

Crystallography has made major contributions to the detailed molecular understanding of resistance in the case of detoxification, mutation and enzyme replacement mechanisms. Splendid examples are:

(*a*) The beta-lactamases: These beta-lactam degrading enzymes, of which there are four classes, are produced by many bacteria to counteract penicillins and cephalosporins, the most widely used antibiotics on the planet. No less than 53 structures of these enzymes reside in the PDB.

(*b*) HIV protease mutations: Tens of mutations have been characterized structurally. Many alter the active site at the site of mutation, thereby preventing drug binding. Other mutations rearrange the protein backbone, reshaping entire pockets in the binding site (Erickson & Burt, 1996).

(*c*) HIV reverse transcriptase mutations: *Via* structural studies, at least three mechanisms of drug resistance have been elucidated: direct alteration of the binding sites for the nucleoside analogue or non-nucleoside inhibitors, mutations that change the position of the DNA template, and mutations that induce conformational changes that propagate into the active site (Das *et al.*, 1996; Hsiou *et al.*, 1998; Huang, Chopra *et al.*, 1998; Ren *et al.*, 1998; Sarafianos *et al.*, 1999).

(*d*) Resistance to vancomycin: In non-resistant bacteria, vancomycin stalls the cell-wall synthesis by binding to the D-Ala-D-Ala terminus of the lipid–PP-disaccharide–pentapeptide substrate of the bacterial transglycosylase/transpeptidase, thereby sterically preventing the approach of the substrate. Resistant bacteria, however, have acquired a plasmid-borne transposon encoding for five genes, *vanS*, *vanR*, *vanH*, *vanA* and *vanX*, that allows them to synthesise a substrate ending in D-Ala-D-lactate. This minute difference, an oxygen atom replacing an NH, leads to a 1000-fold reduced affinity for vancomycin, explaining the resistance (Walsh *et al.*, 1996). Thus far, the structures of vanX (Bussiere *et al.*, 1998) and D-Ala-D-Ala ligase as a model for vanA (Fan *et al.*, 1994) have

Table 1.3.4.2
Protein structures of important human pathogenic bacteria

Organism	Disease(s)	Protein structures solved	Reference
Staphylococcus aureus	Abscesses	Alpha-haemolysin	[1]
	Endocarditis	Aureolysin	[2]
	Gastroenteritis	Beta-lactamase	[3]
	Toxic shock syndrome	Collagen adhesin	[4]
		7,8-Dihydroneopterin aldolase	[5]
		Dihydropteroate synthetase	[6]
		Enterotoxin A	[7]
		Enterotoxin B	[8]
		Enterotoxin C2	[9]
		Enterotoxin C3	[10]
		Exfoliative toxin A	[11]
		Ile-tRNA-synthetase	[12]
		Kanamycin nucleotidyltransferase	[13]
		Leukocidin F	[14]
		Nuclease	[15]
		Staphopain	[16]
		Staphylokinase	[17]
		Toxic shock syndrome toxin-1	[18]
Staphylococcus epidermidis	Implant infections	None	
Enterococcus faecalis	Urinary tract and biliary tract infections	NADH peroxidase	[19]
(*Streptococcus faecalis*)		Histidine-containing phosphocarrier protein	[20]
Streptococcus mutans	Endocarditis	Glyceraldehyde-3-phosphate dehydrogenase	[21]
Streptococcus pneumoniae	Pneumonia	Penicillin-binding protein PBP2x	[22]
	Meningitis, upper respiratory tract infections	Dpnm DNA adenine methyltransferase	[23]
Streptococcus pyogenes	Pharyngitis	Inosine monophosphate dehydrogenase	[24]
	Scarlet fever, toxic shock syndrome, immunologic disorders (acute glomerulonephritis and rheumatic fever)	Pyrogenic exotoxin C	[25]
Bacillus anthracis	Anthrax	Anthrax protective antigen	[26]
Bacillus cereus	Food poisoning	Beta-amylase	[27]
		Beta-lactamase II	[28]
		Neutral protease	[29]
		Oligo-1,6-glucosidase	[30]
		Phospholipase C	[31]
Clostridium botulinum	Botulism	Neurotoxin type A	[32]
Clostridium difficile	Pseudomembranous colitis	None	
Clostridium perfringens	Gas gangrene	Alpha toxin	[33]
	Food poisoning	Perfringolysin O	[34]
Clostridium tetani	Tetanus	Toxin C fragment	[35]
Corynebacterium diphtheriae	Diphtheria	Toxin	[36]
		Toxin repressor	[37]
Listeria monocytogenes	Meningitis, sepsis	Phosphatidylinositol-specific phospholipase C	[38]
Actinomyces israelii	Actinomycosis	None	
Nocardia asteroides	Nocardiosis	None	
Neisseria gonorrhoeae	Gonorrhea	Type 4 pilin	[39]
		Carbonic anhydrase	[40]
Neisseria meningitidis	Meningitis	Dihydrolipoamide dehydrogenase	[41]
Bordetella pertussis	Whooping cough	Toxin	[42]
		Virulence factor P.69	[43]
Brucella sp.	Brucellosis	None	
Campylobacter jejuni	Enterocolitis	None	
Enterobacter cloacae	Urinary tract infection, pneumonia	Beta-lactamase: class C	[44]
		UDP-*N*-acetylglucosamine enolpyruvyltransferase	[45]
Escherichia coli			
ETEC (enterotoxigenic)	Traveller's diarrhoea	Heat-labile enterotoxin	[46]
		Heat-stable enterotoxin (is a peptide)	[47]
EHEC (enterohaemorrhagic)	HUS	Verotoxin-1	[48]
EPEC (enteropathogenic)	Diarrhoea	None	
EAEC (enteroaggregative)	Diarrhoea	None	
EIEC (enteroinvasive)	Diarrhoea	None	
UPEC (uropathogenic)		FimH adhesin	[49]
		FimC chaperone	[49]
		PapD	[50]
NMEC (neonatal meningitis)	Meningitis	None	
Franciscella tularensis	Tularemia	None	
Haemophilus influenzae	Meningitis, otitis media, pneumonia	Diaminopimelate epimerase	[51]
		6-Hydroxymethyl-7,8-dihydropterin pyrophosphokinase	[52]
		Ferric iron binding protein Mirp	[53]
Klebsiella pneumoniae	Urinary tract infection, pneumonia, sepsis	β-Lactamase SHV-1	[54]
Legionella pneumophila	Pneumonia	None	
Pasteurella multocida	Wound infection	None	

Table 1.3.4.2 (continued)

Organism	Disease(s)	Protein structures solved	Reference
Proteus mirabilis	Pneumonia, urinary tract infection	Catalase	[55]
		Glutathione S-transferase	[56]
Proteus vulgaris	Urinary tract infections	Pvu II DNA-(cytosine N4) methyltransferase	[57]
		Pvu II endonuclease	[58]
		Tryptophanase	[59]
Salmonella typhi	Typhoid fever	None, but many for *S. typhimurium* linked with zoonotic disease	
Salmonella enteridis	Enterocolitis	None	
Serratia marcescens	Pneumonia, urinary tract infection	Serralysin	[60]
		Aminoglycoside 3-*N*-acetyltransferase	[61]

Table 1.3.4.3
Protein structures of important human pathogenic protozoa, fungi and helminths

(*a*) Protozoa

Organism	Disease	Protein structures solved	Reference
Acanthamoeba sp.	Opportunistic meningoencephalitis, corneal ulcers	Actophorin	[1]
		Profilin	[2]
Cryptosporidium parvum	Cryptosporidiosis	None	
Entamoeba histolytica	Amoebic dysentery, liver abscesses	None	
Giardia lamblia	Giardiasis	None	
Leishmania sp.	Leishmaniasis	Adenine phosphoribosyltransferase	[3]
		Dihydrofolate reductase-thymidylate synthase	[4]
		Glyceraldehyde-3-phosphate dehydrogenase	[5]
		Leishmanolysin	[6]
		Nucleoside hydrolase	[7]
		Pyruvate kinase	[8]
		Triosephosphate isomerase	[9]
Plasmodium sp.	Malaria	Fructose-1,6-bisphosphate aldolase	[10]
		Lactate dehydrogenase	[11]
		MSP1	[12]
		Plasmepsin II	[13]
		Purine phosphoribosyltransferase	[14]
		Triosephosphate isomerase	[15]
Pneumocystis carinii	Pneumonia	Dihydrofolate reductase	[16]
Toxoplasma gondii	Toxoplasmosis	HGXPRTase	[17]
		UPRTase	[18]
Trichomonas vaginalis	Trichomoniasis	None	
Trypanosoma brucei	Sleeping sickness	Fructose-1,6-bisphosphate aldolase	[19]
		Glyceraldehyde-3-phosphate dehydrogenase	[20]
		6-Phosphogluconate dehydrogenase	[21]
		Phosphoglycerate kinase	[22]
		Triosephosphate isomerase	[23]
		VSG	[24]
Trypanosoma cruzi	Chagas' disease	Cruzain (cruzipain)	[25]
		Glyceraldehyde-3-phosphate dehydrogenase	[26]
		Hypoxanthine phosphoribosyltransferase	[27]
		Triosephosphate isomerase	[28]
		Trypanothione reductase	[29]
		Tyrosine aminotransferase	[30]

(*b*) Fungi

Organism	Disease	Protein structures solved	Reference
Aspergillus fumigatus	Aspergillosis	Restrictocin	[31]
Blastomyces dermatidis	Blastomycosis	None	
Candida albicans	Candidiasis	Dihydrofolate reductase	[32]
		N-Myristoyl transferase	[33]
		Phosphomannose isomerase	[34]
		Secreted Asp protease	[35]
Coccidiodes immitis	Coccidioidomycosis	None	
Cryptococcus neoformans	Cryptococcosis	None	
Histoplasma capsulatum	Histoplasmosis	None	
Mucor sp.	Mucormycosis	None	
Paracoccidioides brasiliensis	Paracoccidioidomycosis	None	
Rhizopus sp.	Phycomycosis	Lipase II	[36]
		Rhizopuspepsin	[37]
		RNase Rh	[38]

been solved. They provide an exciting basis for arriving at new antibiotics against vancomycin-resistant bacteria.

(*e*) DHFR: Some bacteria resort to the 'ultimate mutation' in order to escape the detrimental effects of antibiotics. They simply replace the entire targeted enzyme by a functionally identical but structurally different enzyme. A prime example is the presence of a dimeric plasmid-encoded DHFR in certain trimethoprim-resistant bacteria. The structure proved to be unrelated to that of the chromosomally encoded monomeric DHFR (Narayana *et al.*, 1995).

Clearly, the structural insight gained from these studies provides us with avenues towards methods for coping with the rapid and alarming spread of resistance against available antibiotics that threatens the effective treatment of bacterial infections of essentially every person on this planet. This implies that we will constantly have to be aware of the potential occurrence of mono- and also *multi*-drug resistance, which has profound consequences for drug-design strategies for essentially all infectious diseases. It requires the development of *many* different compounds attacking many different target proteins and nucleic acids in the infectious agent. It appears to be crucial to use, from the very beginning, several new drugs *in combination* so that the chances of the occurrence of resistance are minimal. Multi-drug regimens have been spectacularly successful in the case of leprosy and HIV. Obviously, the development of vaccines is by far the

better solution, but it is not always possible. Antigenic variation, see *e.g.* the influenza virus, requires global vigilance and constant re-engineering of certain vaccines every year. Moreover, for higher organisms, and even for many bacterial species like *Shigella* (Levine & Noriega, 1995), with over 50 serotypes per species, the development of successful vaccines has, unfortunately, proved to be very difficult indeed. For sleeping sickness, the development of a vaccine is generally considered to be impossible. It is most likely, therefore, that world health will depend for centuries on a wealth of therapeutic drugs, together with many other measures, in order to keep the immense number of pathogenic organisms under control.

1.3.4.3. Non-communicable diseases

Of this large and diverse category of human afflictions we have already touched upon genetic disorders in Section 1.3.3 above. Other major types of non-communicable diseases include cancer, aging disorders, diabetes, arthritis, and cardiovascular and neurological illnesses. The field of non-communicable diseases is immense. Describing in any detail the current projects in, and potential impact of, protein and nucleic acid crystallography on these diseases would need more space than this entire volume on macromolecular crystallography. Hence, only a few selected examples out of the hundreds which could be described can be discussed here. Table 1.3.4.5 lists many examples of human protein structures elucidated without any claim as to completeness – it is simply impossible to keep up with the fountain of structures being determined at present. Yet, such tables do provide, it is hoped, an overview of what has been achieved and what needs to be done.

1.3.4.3.1. Cancers

Over a hundred different cancers have been described and clearly the underlying defect, loss of control of cell division, can be the result of many different shortcomings in different cells. The research in this area proceeds at a feverish pace, yet the development, discovery and design of effective but safe anti-cancer agents are unbelievably difficult challenges. The modifications needed to turn a normal cell into a malignant one are very small, hence the chance of arriving at 'true' anti-cancer drugs that exploit such small differences between normal and abnormal cells is exceedingly small. Nevertheless, such selective anti-cancer agents would leave normal cells essentially unaffected and are therefore the holy grail of cancer therapy. Few if any such compounds have been found so far, but cancer therapy is benefiting from a gradual increase in the number of useful compounds. Many have serious side effects, weaken the immune system and are barely tolerated by patients. However, they rescue large numbers of patients and hence it is of interest that many targets of these compounds, proteins and DNA molecules, have been structurally elucidated by crystallographic methods – often in complex with the cancer drug. The mode of action of many anti-cancer compounds is well understood, *e.g.* methotrexate targeting dihydrofolate reductase, and fluorouracil targeting thymidilate synthase. These are specific enzyme inhibitors acting along principles well known in other areas of medicine. Several anti-cancer drugs display unusual modes of action, such as:

(*a*) the DNA intercalators daunomycin (Wang *et al.*, 1987) and adriamycin (Zhang *et al.*, 1993);

(*b*) cisplatin, which forms DNA adducts (Giulian *et al.*, 1996);

Table 1.3.4.4
Mechanisms of resistance

Overexpress target protein
Mutate target protein
Use other protein with same function
Remove target altogether
Overexpress detoxification enzyme
Mutate detoxification enzyme
Create new detoxification enzyme
Mutate membrane porin protein
Remove or underexpress membrane porin protein
Overexpress efflux pumps
Mutate efflux pumps
Create/steal new efflux pumps
Improve DNA repair
Mutate prodrug conversion enzyme

(*c*) taxol, which not only binds to tubulin but also to bcl-2, thereby blocking the machinery of cancer cells in two entirely different ways (Amos & Lowe, 1999);

(*d*) camptothecin analogues, such as irinotecan and topotecan, which have the unusual property of prolonging the lifetime of a covalent topoisomerase–DNA complex, generating major road blocks on the DNA highway and causing DNA breakage and cell death;

(*e*) certain compounds function as minor-groove binders, *e.g.* netropsin and distamycin (Kopka *et al.*, 1985);

(*f*) completely new drugs which were developed based on the structures of matrix metalloproteinases, purine nucleotide phosphorylase and glycinamide ribonucleotide formyltransferase and which are in clinical trials (Jackson, 1997).

Meanwhile, it is sad that crystallography has not yet made any contribution to the molecular understanding of multi-drug resistance in cancer. The resistance is caused by cellular pumps that efficiently pump out the drugs, often leading to failed chemotherapy (Borst, 1999). On the other hand, the structures of major oncogenic proteins such as p21 (DeVos *et al.*, 1988; Pai *et al.*, 1989; Krengel *et al.*, 1990; Scheffzek *et al.*, 1997) and p53 (Cho *et al.*, 1994; Gorina & Pavletich, 1996) are of tremendous importance for future structure-based design of anti-neoplastic agents.

1.3.4.3.2. Diabetes

The hallmark characteristic of type I diabetes is a lack of insulin. A major therapeutic approach to this problem is insulin replacement therapy. Unfortunately, the insulin requirements of the body vary dramatically during the course of a day, with high concentrations needed at meal times and a basal level during the rest of the day. Only monomeric insulin is active at the insulin receptor level, but insulin has a natural tendency to form dimers and hexamers that dissociate upon dilution. Thanks to the three-dimensional insight obtained from dozens of insulin crystal structures, as wild-type (Hodgkin, 1971), mutants (Whittingham *et al.*, 1998) and in complex with zinc ions and small molecules such as phenol (Derewenda *et al.*, 1989), it has been possible to fine-tune the kinetics of insulin dissociation. The resulting availability of a variety of insulin preparations with rapid or prolonged action profiles has improved the quality of life of millions of people (Brange, 1997).

1.3.4.3.3. Blindness

The main causes of blindness worldwide are cataract, trachoma, glaucoma and onchocerciasis (Thylefors *et al.*, 1995). Trachoma and onchocerciasis are parasitic diseases that destroy the architecture of the eye; they were discussed in Section 1.3.4.1. The other two are discussed here. During cataract development, the lens of the eye becomes non-transparent as a result of aggregation of crystallins, preventing image formation. Crystal structures of several mammalian beta- and gamma-crystallins are known, but no human ones yet. In glaucoma, the optic nerve is destroyed by high intra-ocular pressure. One way to lower the pressure is to inhibit carbonic anhydrase II, a pivotal enzyme in maintaining the intra-ocular pressure. On the basis of the carbonic anhydrase crystal structure, researchers at Merck Research Laboratories were able to guide the optimization of an *S*-thienothiopyran-2-sulfonamide lead into a marketed drug for glaucoma: dorzolamide (Baldwin *et al.*, 1989).

1.3.4.3.4. Cardiovascular disorders

Thrombosis is a major cause of morbidity and mortality, especially in the industrial world. Hence, major effort is expended by pharmaceutical industries in the development of new classes of anti-coagulants with fewer side effects than available drugs, such as heparins and coumarins. Because blood coagulation is the result of an amplification cascade of enzymatic reactions, many potential targets are available. At present most of the effort is directed towards thrombin (Weber & Czarniecki, 1997) and factor Xa (Ripka, 1997), responsible for the penultimate step and the step immediately preceding it in the cascade, respectively. Thrombin is especially fascinating owing to the presence of at least three subsites: a primary specificity pocket with the catalytic serine-protease machinery, an exosite for recognizing extended fibrinogen and an additional pocket for binding heparin. This knowledge has led to the design of bivalent inhibitors which occupy two sites with ultra-high affinity and exquisite specificity. Several of these agents are in clinical trials (Pineo & Hull, 1999).

1.3.4.3.5. Neurological disorders

Even a quick glance at Table 1.3.4.5 shows that crystallography contributes to new therapeutics for numerous human afflictions and diseases. Yet there are major gaps in our understanding of protein functions, in particular of those involved in development and in neurological functions. These proteins are the target of many drugs obtained by classical pre-crystal-structure methods. These proven drug targets are very often membrane proteins involved in neuronal functions, and the diseases concerned are some of the most prevalent in mankind. A non-exhaustive list includes cerebrovascular disease (strokes), Parkinson's, epilepsy, schizophrenia, bipolar disease and depression.

Some of these diseases are heart-breaking afflictions, where parents have to accept the suicidal tendencies of their children, often with fatal outcomes; where partners have to endure the tremendous mood swings of their bipolar spouses and have to accept extreme excesses in behaviour; where a happy evening of life is turned into the gradual and sad demise of human intellect due to the progression of Alzheimer's, or to the loss of motor functions due to Parkinson's, or into the tragic stare of a victim of deep depression. Human nature, in all its shortcomings, has the tendency to try to help such tragic victims, but drugs for neurological disorders are rare, drug regimens are difficult to optimize and the commitment to follow a drug regimen – often for years, and often with major side effects – is a next to impossible task in many cases. New, better drugs are urgently needed and hence the structure determinations of the 'molecules of the brain' are major scientific as well as medical challenges of the next decades. Such

Table 1.3.4.5

Important human protein structures in drug design

Proteins from other species that might have been studied as substitutes for human ones were left out because of space limitations. We apologize to the researchers affected.

Pharmacological category	Protein	Reference
Synaptic and neuroeffector junctional function	None	
Central nervous system function	None	
Inflammation	Fibroblast collagenase (MMP-1) (also important in cancer)	[1], [2], [3], [4]
	Gelatinase	[5], [6]
	Stromelysin-1 (MMP-3) (also important in cancer)	[7], [8], [9], [10], [11]
	Matrilysin (MMP-7) (also important in cancer)	[12]
	Neutrophil collagenase (MMP-8) (also important in cancer)	[13], [14], [15], [16]
	Collagenase-3 (MMP-13)	[17]
	Human neutrophil elastase (also important for cystic fibrosis)	[18], [19], [20]
	Interleukin-1 beta converting enzyme (ICE)	[21], [22]
	p38 MAP kinase	[23], [24]
	Phospholipase A2	[25], [26], [27]
Renal and cardiovascular function	Renin	[28]
Gastrointestinal function	None	
Cancer	17-Beta-hydroxysteroid dehydrogenase	[29], [30]
	BRCT domain (BRCA1 C-terminus)	[31]
	Bcr-Abl kinase	[32]
	Cathepsin B	[33]
	Cathepsin D	[34], [35]
	CDK2	[36]
	CDK6	[37]
	DHFR	[38], [39]
	Acidic fibroblast growth factor (FGF)	[40]
	FGF receptor tyrosine kinase domain	[41]
	Glycinamide ribonucleotide formyl transferase	[42]
	Interferon-beta	[43]
	MMPs: see Inflammation	
	p53	[44], [45]
	p60 Src	[46]
	Purine nucleoside phosphorylase	[47]
	ras p21	[48], [49], [50], [51]
	Serine hydroxymethyltransferase	[52]
	S-Adenosylmethionine decarboxylase	[53]
	Thymidylate synthase	[54]
	Topoisomerase I	[55], [56]
	Tumour necrosis factor	[57]
	Interleukin 1-alpha	[58]
	Interleukin 1-beta	[59]
	Interleukin 1-beta receptor	[60], [61]
	Interleukin 8	[62]
Immunomodulation	Calcineurin	[63]
	Cathepsin S	[64]
	Cyclophilin	[65], [66], [67]
	Immunophilin FKBP12	[68], [69], [70]
	Inosine monophosphate dehydrogenase	[71]
	Interferon-gamma	[72], [73]
	Lymphocyte-specific kinase Lck	[74]
	PNP	[47]
	Syk kinase	[75]
	Tumour necrosis factor	[57]
	ZAP Tyr kinase	[76]
	Interleukin 2	[77]
	Interleukin 5	[78]
Haematopoiesis	Erythropoietin receptor	[79], [80]
Coagulation	AT III	[81], [82], [83], [84]
	Factor III	[85], [86]
	Factor VII	[87]
	Factor IX	[88]
	Factor X	[89]
	Factor XIII	[90]
	Factor XIV	[91]
	Fibrinogen: fragment	[92], [93]
	Plasminogen activator inhibitor (PAI)	[94], [95], [96]
	Thrombin	[97], [98], [99]
	tPA	[100]
	Urokinase-type plasminogen activator	[101]
	von Willebrand factor	[102], [103], [104]

molecules will shed light on some of the deepest mysteries of humanity, including memory, cognition, desire, sleep *etc.* At the same time, such structures will provide opportunities for treating those suffering from neurodegenerative diseases due to age, genetic disposition, allergies, infections, traumas and combinations thereof. Such 'CNS protein structures' are one of the major challenges of biomacromolecular crystallography in the 21st century.

1.3.4.4. Drug metabolism and crystallography

As soon as a drug enters the body, an elaborate machinery comes into action to eliminate this foreign and potentially harmful molecule as quickly as possible. Two steps are usually distinguished in this process: phase I metabolism, in which the drug is functionalized, and phase II metabolism, in which further conjugation with endogenous hydrophilic molecules takes place, so that excretion *via* the kidneys can occur. Whereas this 'detoxification' process is essential for survival, it often renders promising inhibitors useless as drug candidates. Hence, structural knowledge of the proteins involved in metabolism could have a significant impact on the drug development process.

Thus far, only the structures of a few proteins crucial for drug distribution and metabolism have been elucidated. Human serum albumin binds hundreds of different drugs with micromolar dissociation constants, thereby altering drug levels in the blood dramatically. The structure of this important carrier molecule has been solved in complex with several drug molecules and should one day allow the prediction of the affinity of new chemical entities for this carrier protein, and thereby deepen our understanding of the serum concentrations of new candidate drugs (Carter & Ho, 1994; Curry *et al.*, 1998; Sugio *et al.*, 1999). Human oxidoreductases and hydrolases of importance in drug metabolism with known structure are: alcohol dehydrogenase (EC 1.1.1.1) (Hurley *et al.*, 1991), aldose reductase (EC 1.1.1.21) (Wilson *et al.*, 1992), glutathione reductase (NADPH) (EC 1.6.4.2) (Thieme *et al.*, 1981), catalase (EC 1.11.1.6) (Ko *et al.*, 2000), myeloperoxidase (EC 1.11.1.7) (Choi *et al.*, 1998) and beta-glucuronidase (EC 3.2.1.31) (Jain *et al.*, 1996). Recently, the first crystal structure of a mammalian cytochrome P-450, the most important class of xenobiotic metabolizing enzymes, has been reported (Williams *et al.*, 2000).

Of the conjugation enzymes, only glutathione S-transferases (EC 2.5.1.18) have been characterized structurally: A1 (Sinning *et al.*, 1993), A4-4 (Bruns *et al.*, 1999), MU-1 (Patskovsky *et al.*, 1999), MU-2 (Raghunathan *et al.*, 1994), P (Reinemer *et al.*, 1992) and THETA-2 (Rossjohn, McKinstry *et al.*, 1998). Tens of structures await elucidation in this area (Testa, 1994).

1.3.4.5. Drug manufacturing and crystallography

The development of drugs is a major undertaking and one of the hallmarks of modern societies. However, once a safe and effective therapeutic agent has been fully tested and approved, manufacturing the compound on a large scale is often the next major challenge. Truly massive quantities of penicillin and cephalosporin are produced worldwide, ranging from 2000 to 7000 tons annually (Conlon *et al.*, 1995). In the production of semi-synthetic penicillins, the enzyme penicillin acylase plays a very significant role. This enzyme catalyses the hydrolysis of penicillin into 6-aminopenicillanic acid. Its crystal structure has been elucidated (Duggleby *et al.*, 1995) and may now be used for protein-engineering studies to improve its properties for the biotechnology industry. The production of cephalosporins could benefit in a similar way from knowing the structure of cephalosporin acylase (CA), since the properties of this enzyme are not optimal for use in production plants. Therefore, the crystal structure determination of CA could provide a basis for improving the substrate specificity of CA by subsequent protein-engineering techniques. Fortunately, a first CA structure has been solved recently (Kim *et al.*, 2000), with many other structures expected to be solved essentially simultaneously. Clearly, crystallography can be not only a major player in the design and optimization of therapeutic drugs, but also in their manufacture.

1.3.5. Vaccines, immunology and crystallography

Vaccines are probably the most effective way of preventing disease. An impressive number of vaccines have been developed and many more are under development (National Institute of Allergy and Infectious Diseases, 1998). Smallpox has been eradicated thanks to a vaccine, and polio is being targeted for eradication in a worldwide effort, again using vaccination strategies. To the best of our knowledge, crystal structures of viruses, viral capsids or viral proteins have not been used in developing the currently available vaccines. However, there are projects underway that may change this.

For instance, the crystal structure of rhinovirus has resulted in the development of compounds that have potential as antiviral agents, since they stabilize the viral capsid and block, or at least delay, the uncoating step in viral cell entry (Fox *et al.*, 1986). These rhinovirus capsid-stabilizing compounds are, in a different project, being used to stabilize poliovirus particles against heat-induced denaturation in vaccines (Grant *et al.*, 1994). This approach may be applicable to other cases, although it has not yet resulted in commercially available vaccine-plus-stabilizer cocktails. However, it is fascinating to see how a drug-design project may be able to assist vaccine development in a rather unexpected manner.

Three-dimensional structural information about viruses is also being used to aid in the development of vaccines. Knowledge of the architecture of and biological functions of coat proteins has been used to select loops at viral surfaces that can be replaced with antigenic loops from other pathogens for vaccine-engineering purposes (*e.g.* Burke *et al.*, 1988; Kohara *et al.*, 1988; Martin *et al.*, 1988; Murray *et al.*, 1998; Arnold *et al.*, 1994; Resnick *et al.*, 1995; Smith *et al.*, 1998; Arnold & Arnold, 1999; Zhang, Geisler *et al.*, 1999). The design of human rhinovirus (HRV) and poliovirus chimeras has been aided by knowing the atomic structure of the viruses (Hogle *et al.*, 1985; Rossmann *et al.*, 1985; Arnold & Rossmann, 1988; Arnold & Rossmann, 1990) and detailed features of the neutralizing immunogenic sites on the virion surfaces (Sherry & Rueckert, 1985; Sherry *et al.*, 1986). In this way, one can imagine that in cases where the atomic structures of antigenic loops in 'donor' immunogens are known as well as the structure of the 'recipient' loop in the virus capsid protein, optimal loop transplantation might become possible. It is not yet known how to engineer precisely the desired three-dimensional structures and properties into macromolecules. However, libraries of macromolecules or viruses constructed using combinatorial mutagenesis can be searched to increase the likelihood of including structures with desired architecture and properties such as immunogenicity. With appropriate selection methods, the rare constructs with desired properties can be identified and 'fished out'. Research of this type has yielded some potently immunogenic presentations of sequences transplanted on the surface of HRV (reviewed in Arnold & Arnold, 1999). For reasons not quite fully understood, presenting multiple copies of antigens to the immune system leads to an enhanced immune response (Malik & Perham, 1997). It is conceivable that, eventually, it might even be possible for conformational epitopes consisting of multiple 'donor' loops to be grafted onto 'recipient capsids' while maintaining the integrity of the original structure. Certainly, such feats are difficult to achieve with present-day protein-engineering skills, but recent successes in protein design offer hope that this will be feasible in the not too distant future (Gordon *et al.*, 1999).

Immense efforts have been made by numerous crystallographers to unravel the structures of molecules involved in the unbelievably complex, powerful and fascinating immune system. Many of the human proteins studied are listed in Table 1.3.4.5 with, as specific highlights, the structures of immunoglobulins (Poljak *et al.*, 1973), major histocompatibility complex (MHC) molecules (Bjorkman *et al.*, 1987; Brown *et al.*, 1993; Fremont *et al.*, 1992; Bjorkman & Burmeister, 1994), T-cell receptors (TCR) and MHC:TCR complexes (Garboczi *et al.*, 1996; Garcia *et al.*, 1996), an array of cytokines and chemokines, and immune cell-specific kinases such as lck (Zhu *et al.*, 1999). This knowledge is being converted into practical applications, for instance by humanising non-human antibodies with desirable properties (Reichmann *et al.*, 1988) and by creating immunotoxins.

The interactions between chemokines and receptors, and the complicated signalling pathways within each immune cell, make it next to impossible to predict the effect of small compounds interfering with a specific protein–protein interaction in the immune system (Deller & Jones, 2000). However, great encouragement has been obtained from the discovery of the remarkable manner by which the immunosuppressor FK506 functions: this small molecule brings two proteins, FKB12 and calcineurin, together, thereby preventing T-cell activation by calcineurin. The structure of this remarkable ternary complex is known (Kissinger *et al.*, 1995). Such discoveries of unusual modes of action of therapeutic compounds are the foundation for new concepts such as 'chemical dimerizers' to activate signalling events in cells such as apoptosis (Clackson *et al.*, 1998).

In spite of the gargantuan task ahead aimed at unravelling the cell-to-cell communication in immune action, it is unavoidable that the next decades will bring us unprecedented insight into the many carefully controlled processes of the immune system. In turn, it is expected that this will lead to new therapeutics for manipulating a truly wonderful defence system in order to assist vaccines, to decrease graft rejection processes in organ transplants and to control auto-immune diseases that are likely to be playing a major role in cruelly debilitating diseases such as rheumatoid arthritis and type I diabetes.

1.3.6. Outlook and dreams

At the beginning of the 1990s, Max Perutz inspired many researchers with a passion for structure and a heart for the suffering of mankind with a fascinating book entitled *Protein Structure – New Approaches to Disease and Therapy* (Perutz, 1992). The explosion of medicinal macromolecular crystallography since then has been truly remarkable. What should we expect for the next decades?

In the realm of safe predictions we can expect the following:

(*a*) High-throughput macromolecular crystallography due to the developments outlined in Section 1.3.1, leading to the new field of 'structural genomics'.

(*b*) Crystallography of very large complexes. While it is now clear that an atomic structure of a complex of 58 proteins and three RNA molecules, the ribosome, is around the corner, crystallographers will widen their horizons and start dreaming of structures like the nuclear pore complex, which has a molecular weight of over 100 000 000 Da.

(*c*) A steady flow of membrane protein structures. Whereas Max Perutz could only list five structures in his book of 1992, there are now over 40 PDB entries for membrane proteins. Most of them are transmembrane proteins: bacteriorhodopsin, photoreaction centres, light-harvesting complexes, cytochrome bc_1 complexes, cytochrome *c* oxidases, photosystem I, porins, ion channels and bacterial toxins such as haemolysin and LukF. Others are monotopic membrane proteins such as squalene synthase and the cyclooxygenases. Clearly, membrane protein crystallography is gaining momentum at present and may open the door to atomic insight in neurotransmitter pharmacology in the next decade.

What if we dream beyond the obvious? One day, medicinal crystallography may contribute to:

(*a*) The design of submacromolecular agonists and antagonists of proteins and nucleic acids in a matter of a day by integrating rapid structure determinations, using only a few nanograms of protein, with the power of combinatorial and, in particular, computational chemistry.

(*b*) 'Structural toxicology' based on 'human structural genomics'. Once the hundreds of thousands of structures of human proteins and complexes with other proteins and nucleic acids have been determined, truly predictive toxicology may become possible. This will not only speed up the drug-development process, but may substantially reduce the suffering of animals in preclinical tests.

(*c*) The creation of completely new classes of drugs to treat addiction, organ regeneration, aging, memory enhancement *etc.*

One day, crystallography will have revealed the structure of hundreds of thousands of proteins and nucleic acids from human and pathogen, and their complexes with each other and with natural and designed low-molecular-weight ligands. This will form an extraordinarily precious database of knowledge for furthering the health of humans. Hence, in the course of the 21st century, crystallography is likely to become a major driving force for improving health care and disease prevention, and will find a well deserved place in future books describing progress in medicine, sometimes called 'The Greatest Benefit to Mankind' (Porter, 1999).

We wish to thank Heidi Singer for terrific support in preparing the manuscript, and Drs Alvin Kwiram, Michael Gelb, Seymour Klebanov, Wes Van Voorhis, Fred Buckner, Youngsoo Kim and Rein Zwierstra for valuable comments.

Chapter 1.4. Perspectives for the future

E. Arnold, M. G. Rossmann, D. M. Himmel, J. C. H. Spence and S. Sun

1.4.1. Gazing into the crystal ball (E. Arnold)

We live in an era when there are many wonderful opportunities for reaching new vistas of human experience. Some of the dreams that we hold may be achieved through scientific progress. Among the things we have learned in scientific research is to expect the unexpected – the crystal ball holds many surprises for us in the future. Alchemists of ancient times laboured to turn ordinary materials into precious metals. These days, scientists can create substances far more precious than gold by discovering new medicines and materials for high-technology industries. Crystallography has played an important role in helping to advance science and the human endeavour in the twentieth century. I expect to see great contributions from crystallography also in the twenty-first century.

Science of the twentieth century has yielded a great deal of insight into the workings of the natural world. Systematic advances are permitting dissection of the molecular anatomy of living systems. This has propelled us into a world where these insights can be brought to bear on problems of design. The impact in such fields as health and medicine, materials science, and microelectronics will be continually greater.

1.4.1.1. What can we expect to see in the future of science and technology in general?

Just as few were successful in predicting the ubiquitous impact of the Internet, it is difficult to predict which specific technologies will accomplish the transition into the culture of the future. It is possible to envision instantaneous telecommunication and videoconferencing with colleagues and friends throughout the world – anytime, anywhere – using small, portable devices. Access to computer-based information *via* media such as the Internet will become continually more facile and powerful. This will permit access to the storehouse of human knowledge in unprecedented ways, catalysing more rapid development of new ideas.

Experimental tests of new ideas will continue to play a crucial role in the guidance of scientific knowledge and reasoning. However, more powerful computing resources may change paradigms in which ever more powerful simulation techniques can bootstrap from primitive ideas to full-blown theories. I still expect that experiment will be necessary for the foreseeable future, since nearly every well designed experiment yields unexpected results, often at a number of levels.

In the realm of biology, greater understanding of the structure and mechanism of living processes will permit unprecedented advances in health and medicine. Even those scientists most sceptical of molecular-design possibilities would be likely to admit that revolutionary advances have been achieved. In the area of drug design, for example, structure-based approaches have yielded some of the most important new molecules currently being introduced worldwide for the treatment of human diseases ranging from AIDS and influenza to cancer and heart disease. This is a relatively young and very rapidly changing area, and it is reasonable to expect that we have witnessed only the tip of the iceberg. Dream drugs to control growth and form, ageing, intelligence, and other physiologically linked aspects of health and well-being may be developed in our lifetime. As greater understanding of the structural basis of immunogenicity emerges, we should also expect to benefit from structure-based approaches to vaccine design.

Other areas where molecular design will play revolutionary roles include the broad field of material sciences. Traditionally, ‘materials science’ referred to the development of materials with desired physical properties – strength, flexibility, and resistance to damage by physical and chemical agents. Now, materials science includes key foci in development of new biomaterials and in the burgeoning field of nanotechnology. The acrobatics of new smart materials could include computation at speeds that may be much faster than can be accomplished with silicon-based materials.

1.4.1.2. How will crystallography change in the future?

Potential future advances in the fields of crystallography, structural chemistry and biology are tantalizing. Owing to the limitations of current physical theories and experimental possibilities, large numbers of molecules have generally been required for detailed investigations of molecular phenomena. Given the complexity of large biological molecules, only techniques such as X-ray crystallography and nuclear magnetic resonance (NMR) have been suitable for describing the detailed atomic structures of these systems. New technologies, unforseen and currently under development, will make the successful imaging of single specimens and single molecules at high resolution far more commonplace than is now achievable. Even now, we are beginning to see X-ray and electron microscopy (EM) methods harnessed to visualize single particles at high resolution. Methods such as coherent X-ray diffraction microscopy (CXDM), discussed in Chapter 9.3 of this volume, and the X-ray (free-electron) laser (XFEL) are challenging the limits of our ability to image single particles directly at high resolution (see Section 1.4.4, below). Merging of information from multiple specimens, as is currently done in electron microscopy, may be very powerful in X-ray microscopy as well.

X-ray sources will continue to evolve. High-intensity synchrotron sources have allowed the development of dramatically faster and higher-quality diffraction data measurements. Complete multiwavelength X-ray diffraction data sets have been measured from frozen protein crystals containing selenomethionine (SeMet) in less than one hour, leading to nearly automatic structure solution by the multiwavelength anomalous diffraction (MAD) technique. At present, such synchrotron facilities are enormous national or multinational facilities that sap the electric power of an entire region. Perhaps portable ‘table-top’ X-ray sources will be developed that can be used to create synchrotron-like intensity in the laboratory. If such sources could have a tunable energy or wavelength, then experiments such as MAD would be routinely accessible within the laboratory. Better time resolution of molecular motion and of chemical reactions will be achieved with higher-intensity sources.

Sample preparation for macromolecular structural studies has undergone a complete revolution thanks to the advent of

Copyright © 2012 International Union of Crystallography

recombinant DNA methods. Early macromolecular studies were limited to materials present in large abundance. By the late 1970s and early 1980s, molecular biology made it possible to obtain desired gene products in large amounts, and new methods of chemical synthesis permitted production of large quantities of defined oligonucleotides. Initial drafts of the entire human genome have been mapped and sequenced, allowing even broader access to genes for study. The combination of structural genomics and already ongoing studies will lead to knowing the structure of the entire human proteome in a finite amount of time. Many materials are still challenging to produce in quantities sufficient for structural studies. Engineering methods (site-directed mutagenesis, combinatorial mutagenesis and directed evolution techniques) have permitted additional sampling of molecular diversity, and we can expect that even more powerful methods will be developed. Engineering of solubility and crystallizability will help make more problems tractable for study. Perhaps, as suggested before, techniques for visualization of single molecules may become adequate for *in situ* visualization of molecular interactions in living cells and organisms. However, traditional considerations of amount, purity, specific activity *etc.* will remain important, as will hard work and good luck.

The phase problem has continued to be a stumbling block for structure determination. Experimental methods, including isomorphous replacement and anomalous-scattering measurements, are currently a mainstay, and will be for the foreseeable future. New isomorphous heavy-atom reagents and preparation methods will emerge; witness the valuable engineering of derivatives *via* mutagenesis to add such heavy-atom-binding sites as cysteine residues in proteins. Anomalous-scattering measurements from macromolecular crystals containing heavy metals or SeMet replacements of methionine residues in proteins have led to tremendous acceleration of the phase-problem solution for many structures – especially in the last two decades with the availability of 'tunable' synchrotron radiation. It should become possible to take better advantage of anomalous-scattering effects from lighter atoms already present in biological molecules: sulfur, phosphorus, oxygen, nitrogen and carbon. The increasingly higher intensity of synchrotron-radiation sources may permit structure solution from microcrystals of macromolecules. Incorporation of non-standard amino acids into proteins will become more common, leading to a vast array of new substitution possibilities. Molecular-replacement phasing from similar structures or from noncrystallographically redundant data is now commonplace and is continuing to become easier. Systematic molecular replacement using all known structures from databases may prove surprisingly powerful, if we can learn how to position small molecular fragments reliably. Systematic molecular-replacement approaches should help identify what folds may be present in a crystalline protein of unknown structure. Direct computational assaults on the phase problem are also becoming more aggressive and successful, although direct-methods approaches still work best for small macromolecular structures with very high resolution data.

Crystallography and structural biology have been helping to drive advances in three-dimensional visualization technology. Versatile molecular-graphics packages have been among the most important software applications for the best three-dimensional graphics workstations. Now that personal computers are being mass-produced with similar graphics capabilities, we are beginning to see a molecular-graphics workstation at every computer, whether desktop or portable (terms that soon may become antiquated since everything will become more compact). Modes of input will include direct access to thought processes, and computer output devices will extend beyond light and sound. Universal Internet access will provide immediate access to the rapidly increasing store of molecular information. As a result, we will achieve a more thorough understanding of patterns present in macromolecular structures: common folds of proteins and nucleic acids, three-dimensional motifs, and evolutionary relationships among molecules. Simulations of complex molecular motions and interactions will be easier to display, making movies of molecules in motion commonplace. Facile 'virtual reality' representation of molecules will be a powerful research and teaching aid. Chemical reaction mechanisms will become better understood over time through interplay among theory, experiment and simulation. The ability to simulate all coupled chemical reactions in living cells and organisms will be achieved over time.

Advances in computational productivity depend on the intricate co-evolution of hardware and software. For silicon-based transistor chips, raw computational speed doubles approximately every 18 months (Moore's law). Tools and software for writing software will continue to advance rapidly. With greater modularity of software tools, it will become easier to coordinate existing programs and program suites. Enhanced automation, parallelization and development of new algorithms will also increase speed and throughput. More powerful software heuristics involving artificial intelligence, expert systems, neural nets and the like may permit unexpected advances in our understanding of the natural world.

In summary, we eagerly await what the future of science and of studies of molecular structure will bring. There is every reason to expect the unexpected. If the past is a guide, many new flowers will bloom to colour our world in bright new ways.

1.4.2. Brief comments on *Gazing into the crystal ball*
(M. G. Rossmann)

Eddy Arnold and I had planned to write a joint commentary about our vision of the future of macromolecular crystallography. However, when Eddy produced the first draft of '*Perspectives for the future*', I was fascinated by his wide vision. I felt it more appropriate and far more interesting to make my own brief comments, stimulated by Eddy's observations.

When I was a graduate student in Scotland in the 1950s, physics departments were called departments of 'Natural Philosophy'. Clearly, the original hope had been that some aspects of science were all encompassing and gave insight to every aspect of observations of natural phenomena. However, in the twentieth century, with rapidly increasing technological advances, it appeared to be more and more difficult for any one person to study all of science. Disciplines were progressively subdivided. Learning became increasingly specialized. *International Tables* were created, and updated, for the use of a highly specialized and small community of crystallographic experts.

As I read Eddy's draft article, I became fascinated by the wide impact he envisioned for crystallography in the next few decades. Indeed, the lay person, reading his article, would barely be aware that this was an article anticipating the future impact of crystallography. The average reader would think that the topic was the total impact of science on our civilization. Thus, to my delight, I saw that crystallography might now be a catalyst for the reunification of fragmented science into a coherent whole. I therefore hope that these new *Tables* commissioned by the International Union of Crystallography may turn out to be a significant help to further the trend implied in Eddy's article.

1.4.3. Additional comments on *Gazing into the crystal ball*
(D. M. Himmel)

I wish to expand briefly on Eddy's and Michael's comments to entertain the question of how macromolecular crystallography and structural biology might change the future. New detector technologies, such as shutterless detector systems that can collect data in continuous rotation mode (see, for example, Miyoshi *et al.*, 2008), are now being developed and deployed at synchrotrons. These detectors will improve the quality of data collection and integration. It is possible that the emergence of ever more rapid and more sensitive X-ray detectors, along with new X-ray technologies, will lead to multiple-wavelength rapidly pulsed X-ray beams that are synchronized by wavelength with the detector. At each crystal rotation position, the beam will rapidly run through each of the several tuned wavelengths and record a diffraction pattern for each wavelength. This sort of setup can be used to collect MAD data from a single data pass through the Ewald sphere. In cases where crystals are particularly sensitive to X-ray damage, this approach, along with the ability to detect anomalous signals from ever-smaller elements in the Periodic Table, may make MAD more competitive with molecular replacement as the method of choice for structure determination. Molecular replacement itself will become more powerful as it is combined with *ab initio* phasing and computational chemistry methods. In the future, due to other emerging technologies such as described in Section 1.4.4 below, whether or not one can crystallize a macromolecule may no longer limit one's ability to determine a structure by X-ray diffraction. Here, I will focus on two additional points: (1) how X-ray crystallography and allied fields (such as NMR and EM) have already started to transform the physical sciences, and (2) how they might transform the overall human experience as well.

In the mid-twentieth century, the physical sciences to a considerable extent were divided into separate fiefdoms that often competed with each other rather than fostered a collaborative spirit. Physics, chemistry, virology and biochemistry, to name a few, each attempted to stand on its own, each using its own independent preferred jargon and preferred explanations for scientific questions of the day. By contrast, what we see happening today is a convergence of all these once-separate fields to understand first principles right down to the molecular level and beyond. More than that, macromolecular crystallography and allied fields are playing a substantial role in catalysing this convergence. The determination and subsequent analysis of a macromolecular structure (such as a protein in complex with nucleic acid, co-factors and/or small-molecule ligands) of necessity culminates from the application of physics, mathematics and chemistry to begin with, followed by various biological sciences to understand the context of a molecular structure. But for physicists, chemists and biologists to speak to each other productively, they increasingly must share the same jargon and learn each other's disciplines. Sir Isaac Newton once wrote, 'If I have seen further it is by standing on the shoulders of giants.' The giants upon which we stand today in crystallography were the leaders of those separate fields that today find their synthesis in the determination and understanding of molecular structure. It is reasonable to assume that this unifying spirit will continue and will foster greater breakthroughs in structure determination and understanding the properties of molecules in the real world.

In addition to bringing various disciplines of science together, macromolecular crystallography and allied fields are likely to revolutionize the way people live in the future. Richard Feynman was reported to have said, 'What I cannot create, I do not understand.' Chapters 3.1, 3.2, and 4.3 of this volume describe the harnessing of gene expression and protein engineering to further the aims of the X-ray crystallographic experiment. Macromolecular engineering, however, does not stop there. Recent years have seen a rising interest in the field of nanotechnology, which, according to some definitions, aims to design machines and technologies that operate on a scale of about 100 nm or smaller (Farokhzad & Langer, 2009). These technologies generally encompass applications of our understanding of chemistry and physics. As this field matures, it will encounter many of the problems on the molecular level that have already been solved by the machines and devices that exist in biological systems, such as enzymes, molecular motors and structural proteins. Proofs of concept have recently been described in which components of biological molecules were redesigned for applications outside their usual environment (Goel & Vogel, 2008; van den Heuvel & Dekker, 2007; Lewis *et al.*, 2011), or in which principles learned from structural biology have been applied to the construction of completely artificial molecular devices (Ceroni *et al.*, 2010). The discoveries of structural biology may well light the way to the nanotechnologies of the future. These technologies, by operating at the molecular level like never before, will enable the manufacture of superior fabrics and materials, improve medical diagnostics, and revolutionize electronics and photonics in a whole host of devices, from computers and robotics to communication and the efficient harnessing of unconventional energy sources like light. Chemical catalysis will be performed in industry with such tight control that there will be far fewer unwanted side reactions than is commonplace today, so that, for example, medicines and other materials can be manufactured cheaply to an exceptionally high level of purity. Drug-delivery vehicles will be developed that precisely target a cell type, tissue type (Farokhzad & Langer, 2009) or even a pathogen. Some of these molecular vehicles will be modelled on methods used by viruses such as influenza, HIV or even bacteriophages, using a harpoon or plasma membrane fusion strategy, and will release their cargo in response to a chemical or other trigger. Others will employ active transport, in which the therapeutic agent will be guided to its target by remote control and carry diagnostics modules for the ride. The development of these nanotechnologies will both benefit from nanotechnological spin-offs of structural studies as well as require X-ray crystallography and other structural techniques to aid in the analysis of the nanomachines.

To peer at an image of individual molecules at atomic or near-atomic resolution, X-ray crystallography has served to provide the missing lens needed to focus that image. New and maturing fields described in the following sections will supply other ways to provide that missing lens, or, indeed, to obtain the initial phase information needed to determine a higher-resolution X-ray crystal structure.

1.4.4. *Gazing into the crystal ball* – the X-ray free-electron laser
(J. C. H. Spence)

The recent invention of the pulsed hard X-ray (free-electron) laser (XFEL) is certain to impact structural biology, particularly in the areas of protein nanocrystal analysis (Chapman *et al.*, 2011), single-particle imaging (Siebert *et al.*, 2011), time-resolved crystallography and solution scattering (see the forthcoming reviews in *Reports on Progress in Physics* by Spence and Chapman). Current hard-X-ray machines provide about 10^{12}

photons in each 40 femtosecond pulse, and are capable of reading out perhaps 120 of the resulting diffraction-pattern 'snapshots' every second. Such a beam, focused to micron dimensions, vaporizes the sample, but it has been discovered that a useful pattern is obtained before radiation damage commences (due to the photoelectron cascade). The method has given 2 Å resolution data from micron-sized protein nanocrystals, and, if sufficiently brief pulses are used, allows about 100 times greater dose to be delivered than the Henderson 'safe dose' (see Chapter 10.3). The snapshot data consist of partial reflections. As a consequence of the fully coherent nature of the radiation, for the smallest submicron nanocrystals the data show interference fringes between the Bragg reflections that facilitate iterative phasing (Spence *et al.*, 2011). Sample delivery has been based on a continuously flowing liquid jet of micron or submicron dimensions, freely flowing in vacuum, with gas focusing at a nozzle to prevent clogging. Merging of millions of nanocrystal snapshots to obtain full reflections has created new challenges for data analysis, as has the development of MAD phasing for the time-resolved absorption involved.

Diffraction patterns may also be obtained from single particles such as a virus or whole cell, commonly injected from a nebulizer in a gas-focused stream into vacuum. Each snapshot gives one projection of the particle in a random orientation, so that three-dimensional reconstruction requires a solution to the difficult problems of orientation determination and phasing of single-particle diffraction patterns. The available X-ray fluence per shot, together with the minimum amount of scattering needed for orientation determination, has so far limited resolution to about 30 nm. However, more powerful X-ray lasers, smaller focused spots and improvements in 'hit rate' are bound to improve resolution to the predicted 1 nm resolution limit for particles too thick for study by cryogenic electron microscopy (cryo-EM). Scattering in the water window, around 500 eV, gives greatly increased protein/water contrast, but wavelength-limited resolution. Conformational variability imposes similar limitations to those encountered in cryo-EM, and the merging of multiple projections from similar cells remains an important challenge for the future, perhaps based on topological constraints. The XFEL also offers unprecedented opportunities for time-resolved imaging, spanning the range from the femtosecond timescale important for electron-transfer reactions in biochemistry, to the slower microsecond processes of protein activity. In favourable cases, a fast optical trigger exists for pump–probe studies, while in others chemical reactions (such as the enzyme cycle) might be followed in mixed and flowing solutions. For this purpose, the correlated fluctuations in 'snapshot' small-angle X-ray (SAX) patterns may prove useful, since they offer a hit rate of 100%. Since these patterns are two-dimensional for particles frozen in space or time, they contain more information than conventional one-dimensional SAX patterns. The ability to reconstruct an image of one particle using the scattering from many randomly oriented particles frozen in space (without modelling) has recently been demonstrated (Saldin *et al.*, 2011). In summary, the XFEL has opened up many new exciting possibilities for structural and dynamic biology, based on entirely new experimental arrangements (now far from optimized) and offering great scope for developments in this highly interdisciplinary field, which spans laser, detector and particle injector physics, diffraction physics, and structural biology. We anticipate rapid progress in methods for the growth of suitable protein microcrystals, especially for membrane proteins. The XFEL is then certain to provide a wealth of new information on molecular mechanisms in biology, as techniques are refined and more powerful X-ray lasers are constructed.

1.4.5. Electron microscopy's impact on structural biology (S. Sun)

Just like crystallography half a century ago, cryo-electron microscopy (cryo-EM) has been developing rapidly and has become one of the dominant techniques in structural biology. Ever since an electron microscope was first constructed, there has been a desire to examine biological samples. There were two major obstacles to this task, one being how to obtain a sample thin enough for the electron beam to go through, the other being the preservation of the sample in the high vacuum of the microscope. Early EM studies of biological specimens combined fixation, dehydration, embedding and sectioning with application of heavy metals to provide contrast in tissue samples. These methods cannot preserve the biological samples in their native state, but merely produce an outline rather than provide intricate three-dimensional structural details. In the 1980s, Dr Jacques Dubochet and his co-workers at the EMBL developed a method of producing vitrified biological samples that made it possible to study biological specimens in their native state (Dubochet *et al.*, 1981, 1988). Together with the invention of high-stability cold stages and transfer mechanisms for electron microscopes, there has been an explosion of studies using cryo-EM for biological samples (Frank, 1989; Ruiz *et al.*, 1994; Frank, 2009; Wade & Hewat, 1994; Ben-Harush *et al.*, 2010).

Single-particle cryo-EM and cryo-electron tomography (cryo-ET) are the most commonly used techniques for the study of biological samples. Owing to the sensitivity to radiation that causes structural damage, only small electron doses can be used to examine biological samples. As a result, the signal-to-noise ratio is low for cryo-EM and especially for cryo-ET. In single-particle cryo-EM, this can be compensated for by collecting two-dimensional (2D) projections of a large number of particles and averaging projections representing the same orientation. Viruses have been among the most popular subjects for single-particle cryo-EM reconstruction because of their high symmetry. With several hundred particles, a 20 Å or so resolution reconstruction can be obtained with relative ease. For particles with low or no symmetry, more data need to be collected to achieve the same resolution. Two of the better-studied asymmetric particles by single particle cryo-EM are the ribosome and GroEL (Frank, 2001; Roseman *et al.*, 2001).

Although the theoretically achievable resolution limit using an electron microscope should be related to the wavelength of the electron beam, in reality there are many factors that affect the resolution, some of which are microscope-related or sample-related. These factors include, but are not limited to, the quality of the microscope, the stability of the sample towards radiation damage, and sample or beam movements caused by electric or magnetic field variation, temperature changes, or mechanical vibrations. It is also essential that the individual samples are sufficiently homogeneous to allow meaningful averaging within the desired resolution. The quality of a specific cryo-EM experimental data set can be judged by the 'Thon rings', provided by the averaged radial Fourier transformation of the particle images. These rings show the averaged resolution limit of the image signal and thus show how far it might be possible to extend the resolution, provided that all relevant parameters are accurately determined. Once the best possible data have been collected on a particular sample, numerous computational steps follow to achieve a good result. These include boxing (selecting particles within a 'box' and normalizing the density to a standard variation), contrast-transfer-function correction, 2D alignment and 3D reconstruction. Many independent groups have developed various software packages for 3D EM reconstruction such as *SPIDER* (see Chapter 19.8), *IMAGIC 4D* (Chapter 19.9), *EMAN* (see Chapter 19.10), *AUTO3DEM* and *FREALIGN* (Ludtke *et al.*, 1999; Shaikh *et al.*, 2008; Yan *et al.*, 2007; Grigorieff, 2007). Numerous aspects of the reconstruction procedure are still being developed to achieve higher resolution, such as individual-particle contrast-transfer-function correction, magnification correction, local refinement in 2D alignment, and averaging among quasi-equivalent subunits within the icosahedral asymmetric unit after the 3D reconstruction. The highest resolution structure obtained for a virus is the 3.1 Å resolution structure of the cytoplasmic polyhedrosis virus.

The definition of resolution of a single-particle cryo-EM reconstruction is different from that used for assessing a crystal structure. The resolution of an EM reconstruction is usually estimated using the 'Fourier shell correlation' method (van Heel & Schatz, 2005). This requires dividing the randomly chosen images into two separate groups and computing reconstructions assuming the previously determined orientations. The resultant maps are then Fourier transformed to permit a comparison of the Fourier amplitudes and phases. The resolution at which the correlation between the amplitudes falls below 0.5 or the average phase difference is greater than 45° is usually a conservative estimate of resolution used by many groups, although other definitions are also in use (Henderson, 2004). Just as is the case for crystallographic maps, the quality of maps at the same resolution can vary depending on the degree of accuracy of the phase determination. Therefore, a visual inspection of a 3D EM map should serve as a useful check.

In contrast to single-particle cryo-EM, cryo-ET can be used to study biological samples that lack homogeneity (Milne & Subramaniam, 2009; Li & Jensen, 2009; Hoenger & McIntosh, 2009; Subramaniam *et al.*, 2007). In this technique, images of the same sample oriented by a succession of tilt angles are taken about a common axis and are subsequently combined into a three-dimensional map. Because the same sample is repeatedly exposed to the electron beam, the allowable electron dose has to be spread over all the tilted images, making the exposure for each image much less than for single-particle cryo-EM. This significantly reduces the limit of achievable resolution. In addition, the physical limitation on the tilt angles results in a 'missing wedge' problem. Dual-axis tomography has been developed to alleviate this problem to some extent. Averaging of the homogeneous portion of the heterogeneous sample has been used when appropriate to increase the resolution of a cryo-ET experiment (Bartesaghi & Subramaniam, 2009).

Cryo-EM methods have been an important addition to the family of structural biology tools. With single-particle cryo-EM, near-atomic-resolution structures can be obtained without the requirement of crystal formation, which is still the rate-limiting step for crystallographic studies. Cryo-ET is particularly useful in studying large molecular complexes and cells that do not possess any symmetry. Further improvements, such as the use of phase plates, further development of automated data-collection software and perfection of reconstruction algorithms, make it likely that cryo-EM will overtake crystallography or NMR as the primary tool for structural biology at low to medium resolution. However, crystallography, NMR and other tools will still be essential to obtain detailed, atomic resolution information.

PART 2. BASIC CRYSTALLOGRAPHY

Chapter 2.1. Introduction to basic crystallography

J. Drenth

2.1.1. Crystals

It is always amazing to see how large molecules, such as proteins, nucleic acids and their complexes, order themselves so neatly in a crystalline arrangement. It is surprising because these large molecules have irregular surfaces with protrusions and cavities, and hydrophilic and hydrophobic spots. Nevertheless, they pack themselves into an orderly arrangement in crystals of millimetre sizes.

Crystals of biological macromolecules are, like most other crystals, not ideal. The X-ray diffraction pattern fades away at diffraction angles corresponding to lattice-plane distances between 1 and 2 Å or even worse. This is not so surprising, since protein crystals are relatively soft. The interaction energy between protein molecules in crystals is of the order of 63×10^{-21} J per protein molecule, or approximately 15 kT (Haas & Drenth, 1995). This corresponds to about ten hydrogen bonds, four salt bridges, or a 400 Å^2 buried hydrophobic surface. Although this energy might not be very different from crystalline interactions between small molecules, the large size of the protein molecules or macromolecular assemblies makes the crystals much more sensitive to distorting forces. Irregularities in the crystal lattice can also stem from the incorporation of impurities – either foreign substances or slightly denatured molecules from the parent protein. Moreover, some molecules may be incorrectly oriented, because the difference in interaction energy between different orientations is rather small. Also, amino-acid side chains assume more than one conformation. These are static irregularities. In addition, dynamic disorder exists: parts of the macromolecule are flexible and affect the X-ray diffraction pattern just as the temperature does.

By neglecting distortions caused by lattice imperfections, crystals are found to have a repeating unit, the unit cell, with basis vectors **a**, **b** and **c**, and angles α, β and γ between them (Fig. 2.1.1.1). The enormous number of unit cells in a crystal are stacked in three dimensions, in an orderly way, with the origins of the unit cells forming a grid or lattice. In Fig. 2.1.1.2, part of a crystalline lattice containing 5 × 3 × 3 unit cells is drawn.

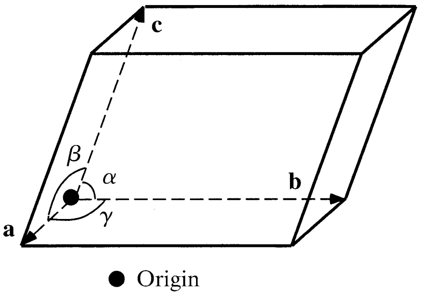

Figure 2.1.1.1
One unit cell with axes **a**, **b** and **c**. The angles between the axes are α, β and γ. Note that the axial system is right-handed. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

It is customary to call the direction along the unit-cell vector **a** the x direction in the lattice; similarly, y is along **b**, and z along **c**.

Crystallographers use a simple system to indicate the planes in a crystal lattice. For instance, the plane containing the unit-cell vectors **a** and **b** is called (001), and the plane containing the vectors **b** and **c** is called (100). The plane (010) contains the vectors **a** and **c**. It should be pointed out that these planes are not limited to one unit cell, but extend through the entire crystal. Moreover, each of these three planes is only one member of a set of parallel and equidistant planes: the set (001), the set (100) and the set (010). For each set, the lattice planes pass through all lattice points, where the lattice points are at the corners of the unit cells (see Fig. 2.1.1.2). Besides the sets of planes (001), (100) and (010), many more sets of parallel and equidistant planes can be drawn through the lattice points. In Fig. 2.1.1.3, this is done for a two-dimensional lattice. Lattice planes always divide the unit-cell vectors **a**, **b** and **c** into a number of equal parts. If the lattice planes divide the **a** vector of the unit cell into h equal parts, the first index for this set of planes is h. The second index, k, is related to the division of **b**, and the third index, l, to the division of **c**. If the set of lattice planes is parallel to a basis unit-cell vector, the corresponding index is 0. Indices for lattice planes are given in parentheses. They should not be confused with directions of vectors connecting lattice points; these are given in square brackets: [uvw], where u is the coordinate in the **a** direction expressed as the number of **a**'s, v in the **b** direction expressed as the number of **b**'s and w in the **c** direction expressed as the number of **c**'s. u, v and w are taken as the simplest set of whole numbers. For instance, [100] is along **a**; [200] has the same direction, but [100] is used instead. [111] points from the origin to the opposite corner of the unit cell.

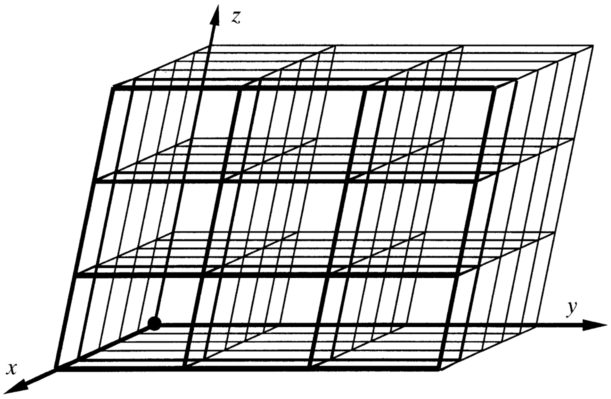

Figure 2.1.1.2
A set of 5 × 3 × 3 unit cells. The points where the lines intersect are called lattice points. The axes x and y form a (001) plane, which is one member of the set of parallel and equidistant (001) planes; y and z form a (100) plane, and z and x a (010) plane. Figure 2.1.1.3

A two-dimensional lattice with 3 × 3 unit cells. In both (*a*) and (*b*), a set of equidistant parallel lattice planes is drawn. They pass through all lattice points. Lattice planes always divide the unit-cell axes into a whole number of equal parts – 1, 2, 3 *etc.* For instance, in (*a*), the vector **a** of the unit cell is cut into two parts, and the vector **b** into only one part. This set of planes is then given the indices $h = 2$ and $k = 1$. In three dimensions, there would be a third index, l. In (*b*), the set of lattice planes has the indices $h = 1$ and $k = 3$. In general, lattice planes have the indices (hkl), known as Miller indices. If a set of lattice planes is parallel to an axis, the corresponding index is 0. For instance, (001) is the set of planes parallel to the unit-cell vectors **a** and **b**. Note that the projection of $\mathbf{a}/h$ on the line normal to the lattice plane is equal to the lattice-plane distance d. This is also true for $\mathbf{b}/k$. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

The choice of the unit cell is not unique and, therefore, guidelines have been established for selecting the standard basis vectors and the origin. They are based on symmetry and metric considerations:

(1) The axial system should be right-handed.
(2) The basis vectors should coincide as much as possible with directions of highest symmetry.
(3) The cell taken should be the smallest one that satisfies condition (2).
(4) Of all lattice vectors, none is shorter than **a**.
(5) Of those not directed along **a**, none is shorter than **b**.
(6) Of those not lying in the *ab* plane, none is shorter than **c**.
(7) The three angles between the basis vectors **a**, **b** and **c** are either all acute (<90°) or all obtuse (≥90°).

It should be noted that the rules for choosing **a**, **b** and **c** are not always obeyed, because of other conventions (see Section 2.1.3). Condition (3) sometimes leads to a centred unit cell instead of a primitive cell. Primitive cells have only one lattice point per unit cell, whereas non-primitive cells contain two or more lattice points. They are designated *A*, *B* or *C* if opposite faces of the cell are centred: *A* for *bc* centring, *B* for *ac* centring and *C* for *ab* centring. If all faces are centred, the designation is *F*, and if the cell is body-centred, it is *I* (Fig. 2.1.1.4).

2.1.2. Symmetry

A symmetry operation can be defined as an operation which, when applied, results in a structure indistinguishable from the original one. According to this definition, the periodic repetition along **a**, **b** and **c** represents translational symmetry.

In addition, rotational symmetry exists, but only rotational angles of 60, 90, 120, 180 and 360° are allowed (*i.e.* rotation over $360/n$ degrees, where n is an integer). These correspond to n-fold rotation axes, with $n = 6, 4, 3, 2$ and 1 (identity), respectively. Rotation axes with $n = 5$ or $n > 6$ are not found as crystallographic symmetry axes, because translations of unit cells containing these axes do not completely fill three-dimensional space. Another type of rotational symmetry axis is the screw axis. It combines a rotation with a translation. For a twofold screw axis, the translation is over 1/2 of the unit-cell length in the direction of the axis; for a threefold screw axis, it is 1/3 or 2/3 *etc.* In this way, the translational symmetry operators can be obeyed. The requirement that translations are 1/2, 1/3, 2/3 *etc.* of the unit-cell length does not exist for individual objects that are not related by crystallographic translational symmetry operators. For instance, an α-helix has 3.6 residues per turn.

Besides translational and rotational symmetry operators, mirror symmetry and inversion symmetry exist. Mathematically, it can be proven that not all combinations of symmetry elements are allowed, but that 230 different combinations can occur. They are the space groups which are discussed extensively in *IT* A (2005). The graphical and printed symbols for the symmetry elements are also found in *IT* A (Chapter 1.4).

Biological macromolecules consist of building blocks such as amino acids or sugars. In general, these building-block structures are not symmetrical and the mirror images of the macromolecules do not exist in nature. Space groups with mirror planes and/or inversion centres are not allowed for crystals of these molecules, because these symmetry operations interchange right and left hands. Biological macromolecules crystallize in one of the 65 enantiomorphic space groups. (Enantiomorphic means the structure is not superimposable on its mirror image.) Apparently, some of these space groups supply more favourable packing conditions for proteins than others. The most favoured space group is $P2_12_12_1$ (Table 2.1.2.1). A consequence of symmetry is

Table 2.1.2.1
The most common space groups for protein crystals

Situation as of April 1997; data extracted from the Protein Data Bank and supplied by Rob Hooft, EMBL Heidelberg.

Space group	Occurrence (%)
$P2_12_12_1$	23
$P2_1$	11
$P3_221$	8
$P2_12_12$	6
$C2$	6

that multiple copies of particles exist in the unit cell. For instance, in space group $P2_1$ (space group No. 4), one can always expect two exactly identical entities in the unit cell, and one half of the unit cell uniquely represents the structure. This unique part of the structure is called the asymmetric unit. Of course, the asymmetric unit does not necessarily contain one protein molecule. Sometimes the unit cell contains fewer molecules than anticipated from the number of asymmetric units. This happens when the molecules occupy a position on a crystallographic axis. This is called a special position. In this situation, the molecule itself obeys the axial symmetry. Otherwise, the molecules in an asymmetric unit are on general positions. There may also be two, three or more equal or nearly equal molecules in the asymmetric unit related by noncrystallographic symmetry.

2.1.3. Point groups and crystal systems

If symmetry can be recognized in the external shape of a body, like a crystal or a virus molecule, corresponding symmetry elements have no translations, because internal translations (if they exist) do not show up in macroscopic properties. Moreover, they pass through one point, and this point is not affected by the symmetry operations (point-group symmetry). For idealized crystal shapes, the symmetry axes are limited to one-, two-, three-, four- and sixfold rotation axes because of the space-filling requirement for crystals. With the addition of mirror planes and inversion centres, there are a total of 32 possible crystallographic point groups.

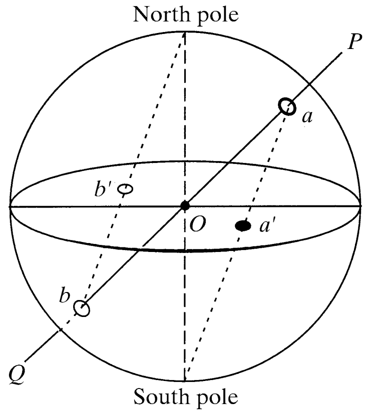

Figure 2.1.3.1
How to construct a stereographic projection. Imagine a sphere around the crystal with O as the centre. O is also the origin of the coordinate system of the crystal. Symmetry elements of the point groups pass through O. Line OP is normal to a crystal plane. It cuts through the sphere at point a. This point a is projected onto the horizontal plane through O in the following way: a vertical dashed line is drawn through O normal to the projection plane and connecting a north and a south pole. Point a is connected to the pole on the other side of the projection plane, the south pole, and is projected onto the horizontal plane at a'. For a normal OQ intersecting the lower part of the sphere, the point of intersection b is connected to the north pole and projected at b'. For the symmetry elements, their points of intersection with the sphere are projected onto the horizontal plane.

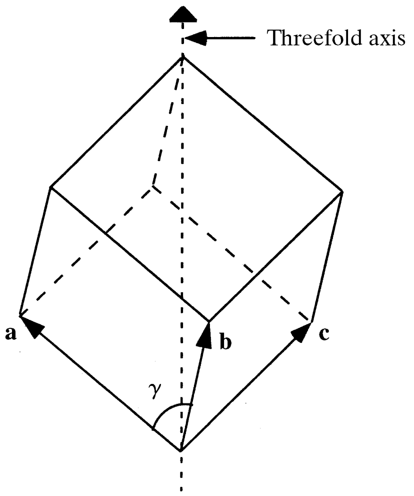

Figure 2.1.3.2
A rhombohedral unit cell.

Not all combinations of axes are allowed. For instance, a combination of two twofold axes at an arbitrary angle with respect to each other would multiply to an infinite number of twofold axes. A twofold axis can only be combined with another twofold axis at 90°. A third twofold axis is then automatically produced perpendicular to the first two (point group 222). In the same way, a threefold axis can only be combined with three twofold axes perpendicular to the threefold axis (point group 32).

For crystals of biological macromolecules, point groups with mirrors or inversion centres are not allowed, because these molecules are chiral. This restricts the number of crystallographic point groups for biological macromolecules to 11; these are the enantiomorphic point groups and are presented in Table 2.1.3.1.

Although the crystals of asymmetric molecules can only belong to one of the 11 enantiomorphic point groups, it is nevertheless important to be aware of the other point groups, especially the 11 centrosymmetric ones (Table 2.1.3.2). This is because if anomalous scattering can be neglected, the X-ray diffraction pattern of a crystal is always centrosymmetric, even if the crystal itself is asymmetric (see Sections 2.1.7 and 2.1.8).

The protein capsids of spherical virus molecules have their subunits packed in a sphere with icosahedral symmetry (532). This is the symmetry of a noncrystallographic point group (Table 2.1.3.3). A fivefold axis is allowed because translation symmetry does not apply to a virus molecule. Application of the 532 symmetry leads to 60 identical subunits in the sphere. This is the simplest type of spherical virus (triangulation number $T = 1$). Larger numbers of subunits can also be incorporated in this icosahedral surface lattice, but then the subunits lie in quasi-equivalent environments and T assumes values of 3, 4 or 7. For instance, for $T = 3$ particles there are 180 identical subunits in quasi-identical environments.

On the basis of their symmetry, the point groups are subdivided into crystal systems as follows. For each of the point groups, a set of axes can be chosen displaying the external symmetry of the crystal as clearly as possible, and, in this way, the seven crystal systems of Table 2.1.3.4 are obtained. If no other symmetry is present apart from translational symmetry, the crystal belongs to the triclinic system. With one twofold axis or screw axis, it is monoclinic. The convention in the monoclinic system is to choose the b axis along the twofold axis. The orthorhombic system

Table 2.1.3.1
The 11 enantiomorphic point groups

The point groups are presented as two stereographic projections (see Fig. 2.1.3.1). On the right is a projection of the symmetry elements, and on the left a projection of the general faces. They are arranged according to the crystal system to which they belong: triclinic, monoclinic *etc*. Different point groups are separated by full horizontal rules. The monoclinic point groups are given in two settings: in the conventional setting with the twofold axis along **b** (unique axis *b*), and the other setting with unique axis *c*. The *b* axis is horizontal in the projection plane, and the *c* axis is normal to the plane. Three-, four- and sixfold axes are always set along the *c* axis, normal to the plane. A special case is the trigonal system; either hexagonal axes or rhombohedral axes can be chosen. In the hexagonal case, the threefold axis is along the *c* axis. The other two axes are chosen along or between the twofold axes, which include an angle of 120°. In the rhombohedral setting, the threefold axis is along the body diagonal of the unit cell, and the unit cell vectors **a**, **b** and **c** are the shortest non-coplanar lattice vectors symmetrically equivalent with respect to the threefold axis (Fig. 2.1.3.2). † A rhombohedral unit cell can be regarded as a cube extended or compressed along the body diagonal (the threefold axis) (see Fig. 2.1.3.2).

has three mutually perpendicular twofold (screw) axes. Another convention is that in tetragonal, trigonal and hexagonal crystals, the axis of highest symmetry is labelled c. These conventions can deviate from the guide rules for unit-cell choice given in Section 2.1.1.

The seven crystal systems are based on the point-group symmetry. Except for the triclinic unit cell, all other cells can occur either as primitive unit cells or as centred unit cells (Section 2.1.1). A total of 14 different types of unit cell exist, depicted in Fig. 2.1.3.3. Their corresponding crystal lattices are commonly called Bravais lattices.

2.1.4. Basic diffraction physics

2.1.4.1. Diffraction by one electron

The scattering of an X-ray beam by a crystal results from interaction between the electric component of the beam and the electrons in the crystal. The magnetic component has hardly any effect and can be disregarded.

If a monochromatic polarized beam hits an electron, the electron starts to oscillate in the direction of the electric vector of the incident beam (Fig. 2.1.4.1). This oscillating electron acts as the aerial of a transmitter and radiates X-rays with the same or lower frequency as the incident beam. The frequency change is due to the Compton effect: the photons of the incident beam collide with the electron and lose part of their energy. This is inelastic scattering, and the scattered radiation is incoherent with the incident beam. Compton scattering contributes to the background in a diffraction experiment. In elastic scattering, the scattered radiation has the same wavelength as the incident

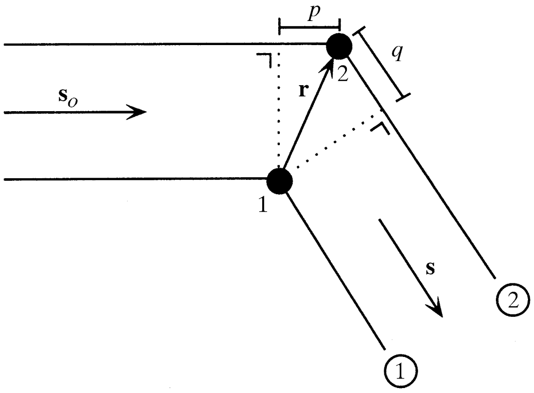

Figure 2.1.4.2
The black dots are electrons. The origin of the system is at electron 1; electron 2 is at position **r**. The electrons are irradiated by an X-ray beam from the direction indicated by vector $\mathbf{s}_o$. The radiation scattered by the electrons is observed in the direction of vector **s**. Because of the path difference $p+q$, scattered beam 2 will lag behind scattered beam 1 in phase. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

radiation, and this is the radiation responsible for the interference effects in diffraction. It was shown by Thomson that if the electron is completely free the following hold:

(1) The phase difference between the incident and the scattered beam is π, because the scattered radiation is proportional to the displacement of the electron, which differs by π in phase with its acceleration imposed by the electric vector.
(2) The amplitude of the electric component of the scattered wave at a distance r which is large in comparison with the wavelength of the radiation is

$$E_{\rm el} = E_o \frac{1}{r}\frac{e^2}{mc^2}\sin\varphi,$$

where E_o is the amplitude of the electric vector of the incident beam, e is the electron charge, m is its mass, c is the speed of light and φ is the angle between the oscillation direction of the electron and the scattering direction (Fig. 2.1.4.1). Note that $E_o \sin\varphi$ is the component of E_o perpendicular to the scattering direction.

In terms of energy,

$$I_{\rm el} = I_o \frac{1}{r^2}\left(\frac{e^2}{mc^2}\right)^2 \sin^2\varphi. \qquad (2.1.4.1a)$$

The scattered energy per unit solid angle is

$$I_{\rm el}(\Omega = 1) = I_{\rm el} r^2. \qquad (2.1.4.1b)$$

It was shown by Klein & Nishina (1929) [see also Heitler (1966)] that the scattering by an electron can be discussed in terms of the classical Thomson scattering if the quantum energy $h\nu \ll mc^2$. This is not true for very short X-ray wavelengths. For $\lambda = 0.0243$ Å, $h\nu$ and mc^2 are exactly equal, but for $\lambda = 1.0$ Å, $h\nu$ is 0.0243 times mc^2. Since wavelengths in macromolecular crystallography are usually in the range 0.8–2.5 Å, the classical approximation is allowed. It should be noted that:

(1) The intensity scattered by a free electron is independent of the wavelength.
(2) Thomson's equation can also be applied to other charged particles, *e.g.* a proton. Because the mass of a proton is 1800 times the electron mass, scattering by protons and by atomic nuclei can be neglected.
(3) Equation (2.1.4.1*a*) gives the scattering for a polarized beam. For an unpolarized beam, $\sin^2\varphi$ is replaced by a suitable polarization factor.

2.1.4.2. *Scattering by a system of two electrons*

This can be derived along classical lines by calculating the phase difference between the X-ray beams scattered by each of the two electrons. A derivation based on quantum mechanics leads exactly to the same result by calculating the transition probability for the scattering of a primary quantum $(h\nu)_o$, given a secondary quantum $h\nu$ (Heitler, 1966, p. 193). For simplification we shall give only the classical derivation here. In Fig. 2.1.4.2, a system of two electrons is drawn with the origin at electron 1 and electron 2 at position **r**. They scatter the incident beam in a direction given by the vector **s**. The direction of the incident beam is along the vector $\mathbf{s}_o$. The length of the vectors can be chosen arbitrarily, but for convenience they are given a length $1/\lambda$. The two electrons scatter completely independently of each other.

Therefore, the amplitudes of the scattered beams 1 and 2 are equal, but they have a phase difference resulting from the path difference between the beam passing through electron 2 and the beam passing through electron 1. The path difference is $p + q = \lambda[\mathbf{r}\cdot(\mathbf{s}_o - \mathbf{s})]$. Beam 2 lags behind in phase compared with beam 1, and with respect to wave 1 its phase angle is

$$-2\pi\lambda[\mathbf{r}\cdot(\mathbf{s}_o - \mathbf{s})]/\lambda = 2\pi\mathbf{r}\cdot\mathbf{S}, \qquad (2.1.4.2)$$

where $\mathbf{S} = \mathbf{s} - \mathbf{s}_o$.

From Fig. 2.1.4.3, it is clear that the direction of **S** is perpendicular to an imaginary plane reflecting the incident beam at an angle θ and that the length of **S** is given by

$$|\mathbf{S}| = 2\sin\theta/\lambda. \qquad (2.1.4.3)$$

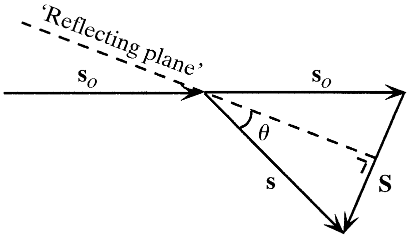

Figure 2.1.4.3
The direction of the incident wave is indicated by $\mathbf{s}_o$ and that of the scattered wave by **s**. Both vectors are of length $1/\lambda$. A plane that makes equal angles with **s** and $\mathbf{s}_o$ can be regarded as a mirror reflecting the incident beam. Reproduced with permission from Drenth (1999). Figure 2.1.4.4
An Argand diagram for the scattering by two electrons. In (*a*), the origin is at electron 1; electron 2 is at position **r** with respect to electron 1. In (*b*), electron 1 is at position **R** with respect to the new origin, and electron 2 is at position $\mathbf{R} + \mathbf{r}$.

The total scattering from the two-electron system is $1 + 1 \times \exp(2\pi i\mathbf{r}\cdot\mathbf{S})$ if the resultant amplitude of the waves from electrons 1 and 2 is set to 1. In an Argand diagram, the waves are represented by vectors in a two-dimensional plane, as in Fig. 2.1.4.4(*a*).[1] Thus far, the origin of the system was chosen at electron 1. Moving the origin to another position simply means an equal change of phase angle for all waves. Neither the amplitudes nor the intensities of the reflected beams change (Fig. 2.1.4.4*b*).

2.1.4.3. *Scattering by atoms*

2.1.4.3.1. *Scattering by one atom*

Electrons in an atom are bound by the nucleus and are – in principle – not free electrons.

However, to a good approximation, they can be regarded as such if the frequency of the incident radiation ν is greater than the natural absorption frequencies, ν_n, at the absorption edges of the scattering atom, or the wavelength of the incident radiation is shorter than the absorption-edge wavelength (Section 2.1.4.4). This is normally true for light atoms but not for heavy ones (Table 2.1.4.1).

Table 2.1.4.1
The position of the $K\alpha$ edge of different elements

Atomic number	Element	$K\alpha$ edge (Å)
6	C	43.68
16	S	5.018
26	Fe	1.743
34	Se	0.980
78	Pt	0.158

If the electrons in an atom can be regarded as free electrons, the scattering amplitude of the atom is a real quantity, because the electron cloud has a centrosymmetric distribution, *i.e.* $\rho(\mathbf{r}) = \rho(-\mathbf{r})$.

A small volume, $\mathrm{d}v_r$, at **r** contains $\rho(\mathbf{r}) \times \mathrm{d}v_r$ electrons, and at $-\mathbf{r}$ there are $\rho(-\mathbf{r}) \times \mathrm{d}v_r$ electrons. The combined scattering of the two volume elements, in units of the scattering of a free electron, is

$$\rho(\mathbf{r})\mathrm{d}v_r\{\exp(2\pi i\mathbf{r}\cdot\mathbf{S}) + \exp[2\pi i(-\mathbf{r})\cdot\mathbf{S}]\} = 2\rho(\mathbf{r})\cos(2\pi\mathbf{r}\cdot\mathbf{S})\mathrm{d}v_r;$$

this is a real quantity.

The scattering amplitude of an atom is called the atomic scattering factor *f*. It expresses the scattering of an atom in terms of the scattering of a single electron. *f* values are calculated for spherically averaged electron-density distributions and, therefore, do not depend on the scattering direction. They are tabulated in *IT* C (2004) as a function of $\sin\theta/\lambda$. The *f* values decrease appreciably as a function of $\sin\theta/\lambda$ (Fig. 2.1.4.5). This is due to interference effects between the scattering from the electrons in the cloud. In the direction $\theta = 0$, all electrons scatter in phase and the atomic scattering factor is equal to the number of electrons in the atom.

2.1.4.3.2. *Scattering by a plane of atoms*

A plane of atoms reflects an X-ray beam with a phase retardation of $\pi/2$ with respect to the scattering by a single atom. The difference is caused by the difference in path length from source (*S*) to atom (*M*) to detector (*D*) for the different atoms in the plane (Fig. 2.1.4.6). Suppose the plane is infinitely large. The shortest connection between *S* and *D via* the plane is *S–M–D*. The plane containing *S*, *M* and *D* is perpendicular to the reflecting plane, and the lines *SM* and *MD* form equal angles with the reflecting plane. Moving outwards from atom *M* in the reflecting plane, to *P* for instance, the path length *S–P–D* is longer. At the edge of the first Fresnel zone, the path is $\lambda/2$ longer (Fig. 2.1.4.6). This edge is an ellipse with its centre at *M* and its major axis on the line of intersection between the plane *SMD* and the reflecting plane. Continuing outwards, many more elliptic Fresnel zones are formed. Clearly, the beams radiated by the many atoms in the plane interfere with each other. The situation is represented in the Argand diagram in Fig. 2.1.4.7. Successive Fresnel zones can be subdivided into an equal number of subzones. If the distribution of electrons is sufficiently homogeneous, it can be assumed that the subzones in one Fresnel zone give the same amplitude at *D*. Their phases are spaced at regular intervals and their vectors in the Argand diagram lie in a half circle. In the lower part of Fig. 2.1.4.7, this is illustrated for the first Fresnel zone. For the second Fresnel zone (upper part),

---

[1] The plane is also called the 'imaginary plane'. The real part of the vector in an Argand diagram is along the horizontal or real axis; the imaginary part is along the vertical or imaginary axis. Note also that $\exp(2\pi i\mathbf{r}\cdot\mathbf{S}) = \cos(2\pi\mathbf{r}\cdot\mathbf{S}) + i\sin(2\pi\mathbf{r}\cdot\mathbf{S})$. The cosine term is the real component and the sine term is the imaginary component.

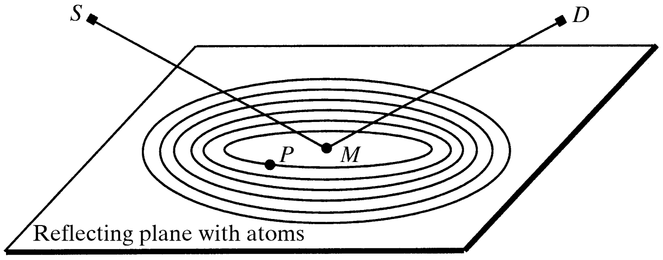

Figure 2.1.4.6
S is the X-ray source and D is the detector. The scattering is by the atoms in a plane. The shortest distance between S and D *via* a point in the plane is through M. Path lengths *via* points in the plane further out from M are longer, and when these beams reach the detector they lag behind in phase with respect to the MD beam. The plane is divided into zones, such that from one zone to the next the path difference is $\lambda/2$.

Endpoint of beams from subzones in the first Fresnel zone

Figure 2.1.4.7
Schematic picture of the Argand diagram for the scattering by atoms in a plane. All electrons are considered free. The vector of the incident beam points to the left. The atom at M (see Fig. 2.1.4.6) has a phase difference of π with respect to the incident beam. Subzones in the first Fresnel zone have the endpoints of their vectors on the lower half circle. For the next Fresnel zone, they are on the upper half circle, which has a smaller radius because the amplitude decreases gradually for subsequent Fresnel zones (Kauzmann, 1957). The sum of all vectors points down, indicating a phase lag of $\pi/2$ with respect to the beam scattered by the atom at M.

the radius is slightly smaller, because the intensity radiated by more distant zones decreases (Kauzmann, 1957). Therefore, the sum of vectors pointing upwards is shorter than that of those pointing downwards, and the resulting scattered wave lags $\pi/2$ in phase behind the scattering by the atom at M.

2.1.4.4. *Anomalous dispersion*

In classical dispersion theory, the scattering power of an atom is derived by supposing that the atom contains dipole oscillators. In units of the scattering of a free electron, the scattering of an oscillator with eigen frequency ν_n and moderate damping factor κ_n was found to be a complex quantity:

$$f_n = \nu^2/(\nu^2 - \nu_n^2 - i\kappa_n\nu), \qquad (2.1.4.4)$$

where ν is the frequency of the incident radiation [James, 1965; see also *IT* C (2004), equation (4.2.6.8)]. When $\nu \gg \nu_n$ in equation (2.1.4.4), f_n approaches unity, as is the case for scattering by a free electron; when $\nu \ll \nu_n$, f_n approaches zero, demonstrating the lack of scattering from a fixed electron. Only for $\nu \cong \nu_n$ does the imaginary part have an appreciable value.

Fortunately, quantum mechanics arrives at the same result by adding a rational meaning to the damping factors and interpreting ν_n as absorption frequencies of the atom (Hönl, 1933). For heavy atoms, the most important transitions are to a continuum of energy states, with $\nu_n \geq \nu_K$ or $\nu_n \geq \nu_L$ *etc.*, where ν_K and ν_L are the frequencies of the K and L absorption edges.

In practice, the complex atomic scattering factor, $f_{\rm anomalous}$, is separated into three parts: $f_{\rm anomalous} = f + f' + if''$. f is the contribution to the scattering if the electrons are free electrons and it is a real number (Section 2.1.4.3). f' is the real part of the correction to be applied and f'' is the imaginary correction; f'' is always $\pi/2$ in phase ahead of f (Fig. 2.1.4.8). $f + f'$ is the total real part of the atomic scattering factor.

The imaginary correction if'' is connected with absorption by oscillators having $\nu_n \cong \nu$. It can be calculated from the atomic absorption coefficient of the anomalously scattering element. For each of the K, L *etc.* absorption edges, f'' is virtually zero for frequencies below the edge, but it rises steeply at the edge and decreases gradually at higher frequencies.

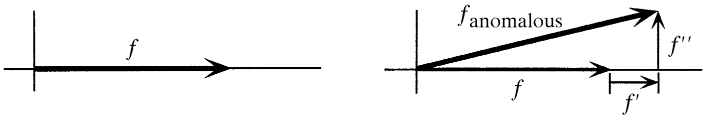
The real correction f' can be derived from f'' by means of the Kramers–Kronig transform [*IT* C (2004), Section 4.2.6.2.2]. For frequencies close to an absorption edge, f' becomes strongly negative.

Values for f, f' and f'' are always given in units equal to the scattering by one free electron. f values are tabulated in *IT* C (2004) as a function of $\sin\theta/\lambda$, and the anomalous-scattering corrections for forward scattering as a function of the wavelength. Because the anomalous contribution to the atomic scattering factor is mainly due to the electrons close to the nucleus, the value of the corrections diminishes much more slowly than f as a function of the scattering angle.

2.1.4.5. *Scattering by a crystal*

A unit cell contains a large number of electrons, especially in the case of biological macromolecules. The waves scattered by these electrons interfere with each other, thereby reducing the effective number of electrons in the scattered wave. The exception is scattering in the forward direction, where the beams from all electrons are in phase and add to each other. The effective number of scattering electrons is called the *structure factor F* because it depends on the structure, *i.e.* the distribution of the atoms in the unit cell. It also depends on the scattering direction. If small electron-density changes due to chemical bonding are neglected, the structure factor can be regarded as the sum of the scattering by the atoms in the unit cell, taking into consideration their positions and the corresponding phase differences between the scattered waves. For n atoms in the unit cell

$$F(\mathbf{S}) = \sum_{j=1}^{n} f_j \exp(2\pi i \mathbf{r}_j \cdot \mathbf{S}), \qquad (2.1.4.5)$$



No anomalous scattering
(*a*)

Anomalous scattering
(*b*)

Figure 2.1.4.8

where **S** is a vector perpendicular to the plane reflecting the incident beam at an angle θ; the length of **S** is given by $|\mathbf{S}| = 2\sin\theta/\lambda$ [equation (2.1.4.3) in Section 2.1.4.2].

The origin of the system is chosen at the origin of the selected unit cell. Atom j is at position $\mathbf{r}_j$ with respect to the origin. Another unit cell has its origin at $t \times \mathbf{a}$, $u \times \mathbf{b}$ and $v \times \mathbf{c}$, where t, u and v are whole numbers, and **a**, **b** and **c** are the basis vectors of the unit cell. With respect to the first origin, its scattering is

$$F(\mathbf{S}) \exp(2\pi i t\mathbf{a} \cdot \mathbf{S}) \exp(2\pi i u\mathbf{b} \cdot \mathbf{S}) \exp(2\pi i v\mathbf{c} \cdot \mathbf{S}).$$

The wave scattered by a crystal is the sum of the waves scattered by all unit cells. Assuming that the crystal has a very large number of unit cells ($n_1 \times n_2 \times n_3$), the amplitude of the wave scattered by the crystal is

$$W_{\rm cr}(\mathbf{S}) = F(\mathbf{S}) \sum_{t=0}^{n_1} \exp(2\pi i t\mathbf{a} \cdot \mathbf{S}) \sum_{u=0}^{n_2} \exp(2\pi i u\mathbf{b} \cdot \mathbf{S}) \times \sum_{v=0}^{n_3} \exp(2\pi i v\mathbf{c} \cdot \mathbf{S}). \qquad (2.1.4.6)$$

For an infinitely large crystal, the three summations over the exponential functions are delta functions. They have the property that they are zero unless

$$\mathbf{a} \cdot \mathbf{S} = h, \ \mathbf{b} \cdot \mathbf{S} = k \text{ and } \mathbf{c} \cdot \mathbf{S} = l, \qquad (2.1.4.7)$$

where h, k and l are whole numbers, either positive, negative or zero. These are the Laue conditions. If they are fulfilled, all unit cells scatter in phase and *the amplitude of the wave scattered by the crystal is proportional to the amplitude of the structure factor F*. Its intensity is proportional to $|F|^2$.

S vectors satisfying equation (2.1.4.7) are denoted by **S**(*hkl*) or **S**(**h**), and the corresponding structure factors as $F(hkl)$ or $F(\mathbf{h})$.

Bragg's law for scattering by a crystal is better known than the Laue conditions:

$$2d \sin\theta = \lambda, \qquad (2.1.4.8)$$

where d is the distance between reflecting lattice planes, θ is the reflecting or glancing angle and λ is the wavelength (Fig. 2.1.4.9). It can easily be shown that the Laue conditions and Bragg's law are equivalent by combining equation (2.1.4.7) with the following information:

(1) Vector **S** is perpendicular to a reflecting plane (Section 2.1.4.2).

(2) The Laue conditions for scattering [equation (2.1.4.7)] can be written as

$$\frac{\mathbf{a}}{h} \cdot \mathbf{S} = 1; \quad \frac{\mathbf{b}}{k} \cdot \mathbf{S} = 1; \quad \frac{\mathbf{c}}{l} \cdot \mathbf{S} = 1. \qquad (2.1.4.9)$$

(3) Lattice planes always divide the unit-cell vectors **a**, **b** and **c** into a number of equal parts (Section 2.1.1). If the lattice planes divide the **a** vector of the unit cell into h equal parts, the first index for this set of planes is h. The second index, k, is related to the division of **b** and the third index, l, to the division of **c**.

From equation (2.1.4.9) it follows that vector **S**(*hkl*) is perpendicular to a plane determined by the points **a**/*h*, **b**/*k* and **c**/*l*, and according to conditions (3) this is a lattice plane. Therefore, scattering by a crystal can indeed be regarded as reflection by lattice planes. The projection of **a**/*h*, **b**/*k* and **c**/*l* on vector **S**(*hkl*) is $1/|\mathbf{S}(hkl)|$ (Laue condition), but it is also equal to the spacing $d(hkl)$ between the lattice planes (see Fig. 2.1.1.3), and, therefore, $|\mathbf{S}(hkl)| = 1/d(hkl)$. Combining this with equation (2.1.4.3) yields Bragg's law, $2d\sin\theta = \lambda$ [equation (2.1.4.8)].

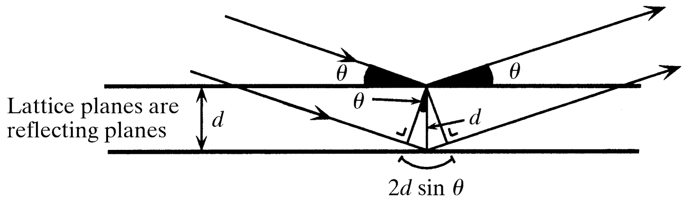

Figure 2.1.4.9
X-ray diffraction by a crystal is, in Bragg's conception, reflection by lattice planes. The beams reflected by successive planes have a path difference of $2d\sin\theta$, where d is the lattice-plane distance and θ is the reflecting angle. Positive interference occurs if $2d\sin\theta = \lambda, 2\lambda, 3\lambda$ *etc.*, where λ is the X-ray wavelength. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

2.1.4.6. *The structure factor*

For noncentrosymmetric structures, the structure factor,

$$F(\mathbf{S}) = \sum_{j=1}^{n} f_j \exp(2\pi i \mathbf{r}_j \cdot \mathbf{S}),$$

is an imaginary quantity and can also be written as[2]

$$F(\mathbf{S}) = \sum_{j=1}^{n} f_j \cos(2\pi \mathbf{r}_j \cdot \mathbf{S}) + i \sum_{j=1}^{n} f_j \sin(2\pi \mathbf{r}_j \cdot \mathbf{S}) = A(\mathbf{S}) + iB(\mathbf{S}).$$

It is sometimes convenient to split the structure factor into its real part, $A(\mathbf{S})$, and its imaginary part, $B(\mathbf{S})$. For centrosymmetric structures, $B(\mathbf{S}) = 0$ if the origin of the structure is chosen at the centre of symmetry.

The average value of the structure-factor amplitude $|F(\mathbf{S})|$ decreases with increasing $|\mathbf{S}|$ or, because $|\mathbf{S}| = 2\sin\theta/\lambda$, with increasing reflecting angle θ.

This is caused by two factors:

(1) A stronger negative interference between the electrons in the atoms at a larger scattering angle; this is expressed in the decrease of the atomic scattering factor as a function of **S**.

(2) The temperature-dependent vibrations of the atoms. Because of these vibrations, the apparent size of an atom is larger during an X-ray exposure, and the decrease in its scattering as a function of **S** is stronger. If the vibration is equally strong in all directions, it is called isotropic, and the atomic scattering factor must be multiplied by a correction factor, the temperature factor, $\exp[-B(\sin^2\theta)/\lambda^2]$. It can be shown that the parameter B is related to the mean-square displacement of the atomic vibrations, $\overline{u^2}$:

$$B = 8\pi^2\overline{u^2}.$$

In protein crystal structures determined at high resolution, each atom is given its own individual thermal parameter B.[3] Anisotropic thermal vibration is described by six parameters instead of one, and the evaluation of this anisotropic thermal vibration requires more data (X-ray intensities) than are usually available. Only at very high resolution (better than 1.5 Å) can one consider the incorporation of anisotropic temperature factors.

---

[2] For convenience, we write $F(\mathbf{S})$ when we mean $F(hkl)$ or $F(\mathbf{h})$, and **S** instead of **S**(*hkl*) or **S**(**h**).

[3] Do not confuse the thermal parameter B with the imaginary part $B(\mathbf{S})$ of the structure factor.

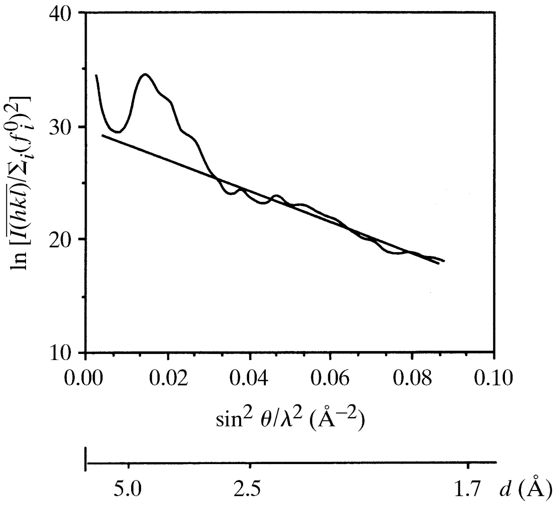

Figure 2.1.4.10
The Wilson plot for phospholipase A_2 with data to 1.7 Å resolution. Only beyond 3 Å resolution is it possible to fit the curve to a straight line. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

The value of $|F(\mathbf{S})|$ can be regarded as the effective number of electrons per unit cell scattering in the direction corresponding to $\mathbf{S}$. This is true if the values of $|F(\mathbf{S})|$ are on an absolute scale; this means that the unit of scattering is the scattering by one electron in a specific direction. The experimental values of $|F(\mathbf{S})|$ are normally on an arbitrary scale. The average value of the scattered intensity, $\overline{I(\text{abs.}, \mathbf{S})}$, on an absolute scale is $\overline{I(\text{abs.}, \mathbf{S})} = \overline{|F(\mathbf{S})|^2} = \sum_i f_i^2$, where f_i is the atomic scattering factor reduced by the temperature factor. This can be understood as follows:

$$\begin{aligned} I(\text{abs.}, \mathbf{S}) &= F(\mathbf{S}) \cdot F^*(\mathbf{S}) = |F(\mathbf{S})|^2 \\ &= \sum_i \sum_j f_i f_j \exp\big[2\pi i(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{S}\big]. \end{aligned} \qquad (2.1.4.10)$$

For a large number of reflections, $\mathbf{S}$ varies considerably, and assuming that the angles $[2\pi(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{S}]$ are evenly distributed over the range 0–2π for $i \neq j$, the average value for the terms with $i \neq j$ will be zero and only the terms with $i = j$ remain, giving

$$\overline{|F(\mathbf{S})|^2} = \overline{I(\text{abs.}, \mathbf{S})} = \sum_i f_i^2. \qquad (2.1.4.11)$$

Because of the thermal vibrations

$$f_i^2 = \exp\big(-2B_i \sin^2\theta/\lambda^2\big)(f_i^o)^2,$$

where i denotes a specific atom and f_i^o is the scattering factor for the atom i at rest.

It is sometimes necessary to transform the intensities and the structure factors from an arbitrary to an absolute scale. Wilson (1942) proposed a method for estimating the required scale factor K and, as an additional bonus, the thermal parameter B averaged over the atoms:

$$\overline{I(\mathbf{S})} = K\overline{I(\text{abs.}, \mathbf{S})} = K \exp(-2B \sin^2\theta/\lambda^2) \sum_i (f_i^o)^2. \qquad (2.1.4.12)$$

To determine K and B, equation (2.1.4.11) is written in the form

$$\ln[\overline{I(\mathbf{S})}/ \textstyle\sum_i (f_i^o)^2] = \ln K - 2B \sin^2\theta/\lambda^2. \qquad (2.1.4.13)$$

Because f_i^o depends on $\sin\theta/\lambda$, average intensities, $\overline{I(\mathbf{S})}$, are calculated for shells of narrow $\sin\theta/\lambda$ ranges. $\ln[\overline{I(\mathbf{S})}/ \sum_i (f_i^o)^2]$ is plotted against $\sin^2\theta/\lambda^2$. The result should be a straight line with slope $-2B$, intersecting the vertical axis at ln K (Fig. 2.1.4.10).

For proteins, the Wilson plot gives rather poor results because the assumption in deriving equation (2.1.4.11) that the angles, $[2\pi(\mathbf{r}_i - \mathbf{r}_j) \cdot \mathbf{S}]$, are evenly distributed over the range 0–2π for $i \neq j$ is not quite valid, especially not in the $\sin\theta/\lambda$ ranges at low resolution.

As discussed above, the average value of the structure factors, $F(\mathbf{S})$, decreases with the scattering angle because of two effects:

(1) the decrease in the atomic scattering factor f;
(2) the temperature factor.

This decrease is disturbing for statistical studies of structure-factor amplitudes. It is then an advantage to eliminate these effects by working with normalized structure factors, $E(\mathbf{S})$, defined by

$$\begin{aligned} E(\mathbf{S}) &= F(\mathbf{S}) \Big/ \Big(\sum_j f_j^2\Big)^{1/2} \\ &= F(\mathbf{S}) \exp\big(B \sin^2\theta/\lambda^2\big) \Big/ \Big[\sum_j (f_j^o)^2\Big]^{1/2}. \end{aligned} \qquad (2.1.4.14)$$

The application of equation (2.1.4.14) to $\overline{|E(\mathbf{S})|^2}$ gives

$$\overline{|E(\mathbf{S})|^2} = \overline{|F(\mathbf{S})|^2} \Big/ \sum_j f_j^2 = \overline{|F(\mathbf{S})|^2} \Big/ \overline{|F(\mathbf{S})|^2} = 1. \qquad (2.1.4.15)$$

The average value, $\overline{|E(\mathbf{S})|^2}$, is equal to 1. The advantage of working with normalized structure factors is that the scaling is not important, because if equation (2.1.4.14) is written as

$$E(\mathbf{S}) = \frac{F(\mathbf{S})}{(\overline{|F(\mathbf{S})|^2})^{1/2}},$$

a scale factor affects numerator and denominator equally.

In practice, the normalized structure factors are derived from the observed data as follows:

$$E(\mathbf{S}) = F(\mathbf{S}) \exp\big(B \sin^2\theta/\lambda^2\big) \big/ \big(\varepsilon \overline{|F(\mathbf{S})|^2}\big)^{1/2}, \qquad (2.1.4.16)$$

where ε is a correction factor for space-group symmetry. For general reflections it is 1, but it is greater than 1 for reflections having $\mathbf{h}$ parallel to a symmetry element. This can be understood as follows. For example, if m atoms are related by this symmetry element, $\mathbf{r}_j \cdot \mathbf{S}$ (with j from 1 to m) is the same in their contribution to the structure factor

$$F(\mathbf{h}) = \sum_{j=1}^{m} f_j \exp(2\pi i \mathbf{r}_j \cdot \mathbf{S}).$$

They act as one atom with scattering factor $m \times f$ rather than as m different atoms, each with scattering factor f. According to equation (2.1.4.11), this increases $F(\mathbf{h})$ by a factor $m^{1/2}$ on average. To make the F values of all reflections statistically comparable, $F(\mathbf{h})$ must be divided by $m^{1/2}$. For a detailed discussion, see *IT* B (2008), Chapter 2.1, by U. Shmueli and A. J. C. Wilson.

2.1.5. Reciprocal space and the Ewald sphere

A most convenient tool in X-ray crystallography is the reciprocal lattice. Unlike real or direct space, reciprocal space is imaginary. The reciprocal lattice is a superior instrument for constructing the X-ray diffraction pattern, and it will be introduced in the following way. Remember that vector $\mathbf{S}(hkl)$ is perpendicular to a reflecting plane and has a length $|\mathbf{S}(hkl)| = 2\sin\theta/\lambda = 1/d(hkl)$ (Section 2.1.4.5). This will now be applied to the boundary planes of the unit cell: the *bc* plane or (100), the *ac* plane or (010) and the *ab* plane or (001).

For the *bc* plane or (100): indices $h = 1$, $k = 0$ and $l = 0$; $\mathbf{S}(100)$ is normal to this plane and has a length $1/d(100)$. Vector $\mathbf{S}(100)$ will be called $\mathbf{a}^*$.

For the *ac* plane or (010): indices $h = 0$, $k = 1$ and $l = 0$; $\mathbf{S}(010)$ is normal to this plane and has a length $1/d(010)$. Vector $\mathbf{S}(010)$ will be called $\mathbf{b}^*$.

For the *ab* plane or (001): indices $h = 0$, $k = 0$ and $l = 1$; $\mathbf{S}(001)$ is normal to this plane and has a length $1/d(001)$. Vector $\mathbf{S}(001)$ will be called $\mathbf{c}^*$.

From the definition of $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$ and the Laue conditions [equation (2.1.4.7)], the following properties of the vectors $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$ can be derived:

$$\mathbf{a}^* \cdot \mathbf{a} = \mathbf{a} \cdot \mathbf{a}^* = \mathbf{a} \cdot \mathbf{S}(100) = h = 1.$$

Similarly

$$\mathbf{b}^* \cdot \mathbf{b} = \mathbf{b} \cdot \mathbf{S}(010) = k = 1,$$

and

$$\mathbf{c}^* \cdot \mathbf{c} = \mathbf{c} \cdot \mathbf{S}(001) = l = 1.$$

However, $\mathbf{a}^* \cdot \mathbf{b} = 0$ and $\mathbf{a}^* \cdot \mathbf{c} = 0$ because $\mathbf{a}^*$ is perpendicular to the (100) plane, which contains the *b* and *c* axes. Correspondingly, $\mathbf{b}^* \cdot \mathbf{a} = \mathbf{b}^* \cdot \mathbf{c} = 0$ and $\mathbf{c}^* \cdot \mathbf{a} = \mathbf{c}^* \cdot \mathbf{b} = 0$.

Proposition. The endpoints of the vectors $\mathbf{S}(hkl)$ form the points of a lattice constructed with the unit vectors $\mathbf{a}^*$, $\mathbf{b}^*$ and $\mathbf{c}^*$.

Proof. Vector $\mathbf{S}$ can be split into its coordinates along the three directions a^*, b^* and c^*:

$$\mathbf{S} = X \cdot \mathbf{a}^* + Y \cdot \mathbf{b}^* + Z \cdot \mathbf{c}^*. \tag{2.1.5.1}$$

Our proposition is true if X, Y and Z are whole numbers and indeed they are. Multiply equation (2.1.5.1) on the left and right side by $\mathbf{a}$.

$$\begin{array}{ccccccc} \mathbf{a} \cdot \mathbf{S} = & X \cdot \mathbf{a} \cdot \mathbf{a}^* & + & Y \cdot \mathbf{a} \cdot \mathbf{b}^* & + & Z \cdot \mathbf{a} \cdot \mathbf{c}^* \\ \vdots & \vdots & & \vdots & & \vdots \\ = h & = X \cdot 1 & & = 0 & & = 0. \end{array}$$

The conclusion is that $X = h$, $Y = k$ and $Z = l$, and, therefore,

$$\mathbf{S} = h \cdot \mathbf{a}^* + k \cdot \mathbf{b}^* + l \cdot \mathbf{c}^*.$$

The diffraction by a crystal [equation (2.1.4.6)] is only different from zero if the Laue conditions [equation (2.1.4.7)] are satisfied. All vectors $\mathbf{S}(hkl)$ are vectors in reciprocal space ending in reciprocal-lattice points and not in between. Each vector $\mathbf{S}(hkl)$ is normal to the set of planes (hkl) in real space and has a length $1/d(hkl)$ (Fig. 2.1.5.1).

The reciprocal-lattice concept is most useful in constructing the directions of diffraction. The procedure is as follows:

Step 1: Draw the vector $\mathbf{s}_o$ indicating the direction of the incident beam from a point M to the origin, O, of the reciprocal lattice. As in Section 2.1.4.2, the length of $\mathbf{s}_o$ and thus the distance MO is $1/\lambda$ (Fig. 2.1.5.2).

Step 2: Construct a sphere with radius $1/\lambda$ and centre M. The sphere is called the Ewald sphere. The scattering object is thought to be placed at M.

Step 3: Move a reciprocal-lattice point P to the surface of the sphere. Reflection occurs with $\mathbf{s} = \mathbf{MP}$ as the reflected beam, but only if the reciprocal-lattice point P is on the surface of the sphere, because only then does $\mathbf{S}(hkl) = \mathbf{s} - \mathbf{s}_o$ (Section 2.1.4.2).

Noncrystalline objects scatter differently. Their scattered waves are not restricted to reciprocal-lattice points passing through the Ewald sphere. They scatter in all directions.

2.1.6. Mosaicity and integrated reflection intensity

Crystals hardly ever have a perfect arrangement of their molecules, and crystals of macromolecules are certainly not perfect. Their crystal lattices show defects, which can sometimes be observed with an atomic force microscope or by interferometry. A schematic but useful way of looking at non-perfect crystals is through mosaicity; the crystal consists of a large number of tiny blocks. Each block is regarded as a perfect crystal, but the blocks are slightly misaligned with respect to each other. Scattering from different blocks is incoherent. Mosaicity causes a spread in the diffracted beams; when combined with the divergence of the beam from the X-ray source, this is called the effective mosaic spread. For the same crystal, effective mosaicity is smaller in a synchrotron beam with its lower divergence than in the laboratory. Protein crystals usually show a mosaic spread of 0.25–0.5°. Mosaic spread increases due to distortion of the lattice; this can happen as a result of flash freezing or radiation damage, for instance.

In Section 2.1.4.5, it was stated that the amplitude of the wave scattered by a crystal is proportional to the structure-factor amplitude $|F|$ and that its intensity is proportional to $|F|^2$. Of course, other factors also determine the intensity of the scattered beam, such as the wavelength, the intensity of the incident beam, the volume of the crystal *etc.* The intensity integrated over the entire region of the diffraction spot *hkl* is

$$I_{\rm int}(hkl) = \frac{\lambda^3}{\omega V^2}\left(\frac{e^2}{mc^2}\right)^2 V_{\rm cr} I_o LPT|F(hkl)|^2. \tag{2.1.6.1}$$

In equation (2.1.6.1), we recognize $I_o(e^2/mc^2)^2$ as part of the Thomson scattering for one electron, $I_{\rm el} = I_o(e^2/mc^2)^2 \sin^2\varphi$ [equations (2.1.4.1*a*) and (2.1.4.1*b*)] per unit solid angle. $V_{\rm cr}$ is the

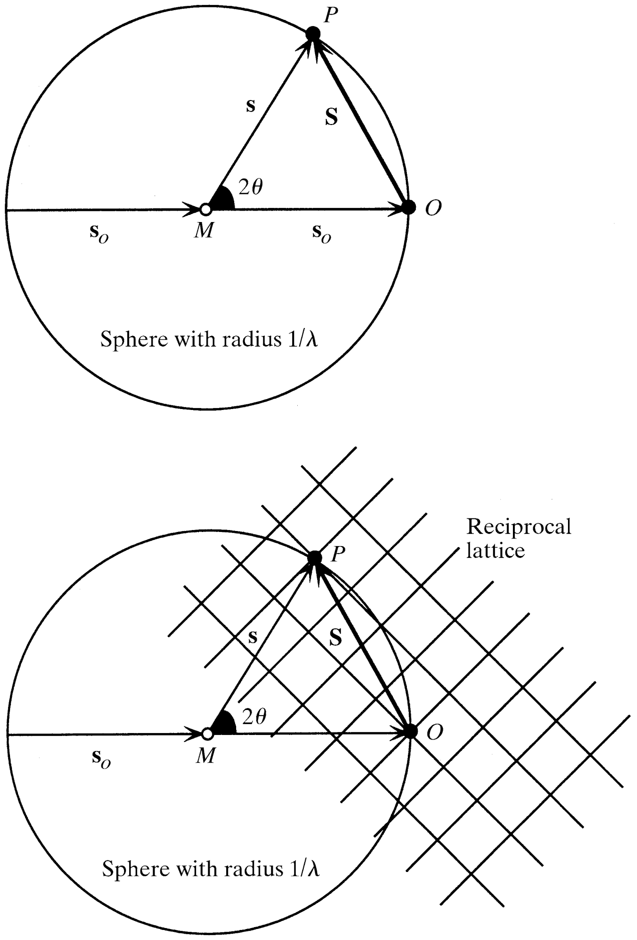

Figure 2.1.5.2
The circle is, in fact, a sphere with radius $1/\lambda$. $\mathbf{s}_O$ indicates the direction of the incident beam and has a length $1/\lambda$. The diffracted beam is indicated by vector **s**, which also has a length $1/\lambda$. Only reciprocal-lattice points on the surface of the sphere are in a reflecting position. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

volume of the crystal and V is the volume of the unit cell. It is clear that the scattered intensity is proportional to the volume of the crystal. The term $1/V^2$ can be explained as follows. In a mosaic block, all unit cells scatter in phase. For a given volume of the individual blocks, the number of unit cells in a mosaic block, as well as the scattering amplitude, is proportional to $1/V$. The scattered intensity is then proportional to $1/V^2$. Because of the finite reflection width, scattering occurs not only for the reciprocal-lattice point when it is on the Ewald sphere, but also for a small volume around it. Since the sphere has radius $1/\lambda$, the solid angle for scattering, and thus the intensity, is proportional to $1/(1/\lambda)^2 = \lambda^2$.

However, in equation (2.1.6.1), the scattered intensity is proportional to λ^3. The extra λ dependence is related to the time t it takes for the reciprocal-lattice 'point' to pass through the surface of the Ewald sphere. With an angular speed of rotation ω, a reciprocal-lattice point at a distance $1/d$ from the origin of the reciprocal lattice moves with a linear speed $v = (1/d)\omega$ if the rotation axis is normal to the plane containing the incident and reflected beam. For the actual passage through the surface of the Ewald sphere, the component perpendicular to the surface is needed: $v_\perp = (1/d)\omega\cos\theta = \omega\sin 2\theta/\lambda$. Therefore, the time t required to pass through the surface is proportional to $(1/\omega)(\lambda/\sin 2\theta)$. This introduces the extra λ term in equation (2.1.6.1) as well as the ω dependence and a $1/\sin 2\theta$ term. The latter represents the Lorentz factor L. It is a geometric correction factor for the *hkl* reflections; here it is $1/\sin 2\theta$, but it is different for other data-collection geometries.

The factor P in equation (2.1.6.1) is the polarization factor. For the polarized incident beam used in deriving equation (2.1.4.1*a*), $P = \sin^2\varphi$, where φ is the angle between the polarization direction of the beam and the scattering direction. It is easy to verify that $\phi = 90^\circ - 2\theta$, where θ is the reflecting angle (Fig. 2.1.4.9). P depends on the degree of polarization of the incident beam. For a completely unpolarized beam, $P = (1 + \cos^2 2\theta)/2$.

In equation (2.1.6.1), T is the transmission factor: $T = 1 - A$, where A is the absorption factor. When X-rays travel through matter, they suffer absorption. The overall absorption follows Beer's law:

$$I = I_o \exp(-\mu d),$$

where I_o is the intensity of the incident beam, d is the path length in the material and μ is the total linear absorption coefficient. μ can be obtained as the sum of the atomic mass absorption coefficients of the elements $(\mu_m)_i$:

$$\mu = \rho \sum_i g_i(\mu_m)_i,$$

where ρ is the density of the absorbing material and g_i is the mass fraction of element i.

Atomic mass absorption coefficients $(\mu_m)_i$ for the elements are listed in Tables 4.2.4.3 (and 4.2.4.1) of *IT* C (2004) as a function of a large number of wavelengths. The absorption is wavelength-dependent and is generally much stronger for longer wavelengths. This is the result of several processes. For the X-ray wavelengths applied in crystallography, the processes are scattering and photoelectric absorption. Moreover, at the reflection position, the intensity may be reduced by extinction.

Scattering is the result of a collision between the X-ray photons and the electrons. One can distinguish two kinds of scattering: Compton scattering and Rayleigh scattering. In Compton scattering, the photons lose part of their energy in the collision process (inelastic scattering), resulting in scattered photons with a lower energy and a longer wavelength. Compton scattering contributes to the background in an X-ray diffraction experiment. In Rayleigh scattering, the photons are elastically scattered, do not lose energy, and leave the material with their wavelength unchanged. In a crystal, they interfere with each other and give rise to the Bragg reflections. Between the Bragg reflections, there is no loss of energy due to elastic scattering and the incident beam is hardly reduced. In the Bragg positions, if the reduction in intensity of the incident beam due to elastic scattering can still be neglected, the crystal is considered an ideal mosaic. For non-ideal mosaic crystals, the beam intensity is reduced by *extinction*:

(1) The blocks are too large, and multiple reflection occurs within a block. At each reflection process, the phase angle shifts $\pi/2$ (Section 2.1.4.3.2). After two reflections, the beam travels in the same direction as the incident beam but with a phase difference of π, and this reduces the intensity.
(2) The angular spread of the blocks is too small. The incident beam is partly reflected by blocks close to the surface and the resulting beam is the incident beam for the lower-lying blocks that are also in reflecting position.

Extinction is not a serious problem in protein X-ray crystallography.

Absorption curves as a function of the X-ray wavelength show anomalies at absorption edges. At such an edge, electrons are ejected from the atom or are elevated to a higher-energy bound state, the photons disappear completely and the X-ray beam is strongly absorbed. This is called *photoelectric absorption*. At an absorption edge, the frequency of the X-ray beam ν is equal to the frequency ν_K, ν_L or ν_M corresponding to the energy of the K, L or M state. According to equation (2.1.4.4), anomalous scattering is maximal at an absorption edge.

2.1.7. Calculation of electron density

In equation (2.1.4.6), the wave $W_{\rm cr}(\mathbf{S})$ scattered by the crystal is given as the sum of the atomic contributions, as in equation (2.1.4.5) for the scattering by a unit cell. In the derivation of equation (2.1.4.5), it is assumed that the atoms are spherically symmetric (Section 2.1.4.3) and that density changes due to chemical bonding are neglected. A more exact expression for the wave scattered by a crystal, in the absence of anomalous scattering, is

$$W_{\rm cr}(\mathbf{S}) = \int_{\rm crystal} \rho(\mathbf{r}) \exp(2\pi i \mathbf{r}\cdot\mathbf{S})\, {\rm d}v_{\rm real}. \tag{2.1.7.1}$$

The integration is over all electrons in the crystal. $\rho(\mathbf{r})$ is the electron-density distribution in each unit cell. The operation on the electron-density distribution in equation (2.1.7.1) is called Fourier transformation, and $W_{\rm cr}(\mathbf{S})$ is the Fourier transform of $\rho(\mathbf{r})$. It can be shown that $\rho(\mathbf{r})$ is obtained by an inverse Fourier transformation:

$$\rho(\mathbf{r}) = \int_{\mathbf{S}} W_{\rm cr}(\mathbf{S}) \exp(-2\pi i \mathbf{r}\cdot\mathbf{S})\, {\rm d}v_{\rm reciprocal}. \tag{2.1.7.2}$$

In contrast to $\rho(\mathbf{r})$, $W_{\rm cr}(\mathbf{S})$ is not a continuous function but, because of the Laue conditions, it is only different from zero at the reciprocal-lattice points $\mathbf{h}$ $(= hkl)$. In equation (2.1.4.6), $W_{\rm cr}(\mathbf{S})$ is the product of the structure factor and three delta functions. The structure factor at the reciprocal-lattice points is $F(\mathbf{h})$, and the product of the three delta functions is $1/V$, the volume of one reciprocal unit cell. Therefore, $W_{\rm cr}(\mathbf{S})$ in equation (2.1.7.2) can be replaced by $F(\mathbf{h})/V$, and equation (2.1.7.2) itself by

$$\rho(\mathbf{r}) = (1/V) \sum_{\mathbf{h}} F(\mathbf{h}) \exp(-2\pi i \mathbf{r}\cdot\mathbf{h}). \tag{2.1.7.3}$$

If x, y and z are fractional coordinates in the unit cell, $\mathbf{r}\cdot\mathbf{S} = (\mathbf{a}\cdot x + \mathbf{b}\cdot y + \mathbf{c}\cdot z)\cdot\mathbf{S} = \mathbf{a}\cdot\mathbf{S}\cdot x + \mathbf{b}\cdot\mathbf{S}\cdot y + \mathbf{c}\cdot\mathbf{S}\cdot z = hx + ky + lz$, and an alternative expression for the electron density is

$$\rho(xyz) = (1/V) \sum_h \sum_k \sum_l F(hkl) \exp[-2\pi i(hx + ky + lz)]. \tag{2.1.7.4}$$

Instead of expressing $F(\mathbf{S})$ as a summation over the atoms [equation (2.1.4.5)], it can be expressed as an integration over the electron density in the unit cell:

$$F(hkl) = V \int_{x=0}^{1} \int_{y=0}^{1} \int_{z=0}^{1} \rho(xyz) \exp[2\pi i(hx + ky + lz)]\, {\rm d}x\, {\rm d}y\, {\rm d}z. \tag{2.1.7.5}$$

Because $F(hkl)$ is a vector in the Argand diagram with an amplitude $|F(hkl)|$ and a phase angle $\alpha(hkl)$,

$$F(hkl) = |F(hkl)| \exp[i\alpha(hkl)]$$

and

$$\rho(xyz) = (1/V) \sum_h \sum_k \sum_l |F(hkl)| \exp[-2\pi i(hx + ky + lz) + i\alpha(hkl)]. \tag{2.1.7.6}$$

By applying equation (2.1.7.6), the electron-density distribution in the unit cell can be calculated, provided values of $|F(hkl)|$ and $\alpha(hkl)$ are known. From equation (2.1.6.1), it is clear that $|F(hkl)|$ can be derived, on a relative scale, from $I_{\rm int}(hkl)$ after a correction for the background and absorption, and after application of the Lorentz and polarization factor:

$$|F(hkl)| = \left[\frac{I_{\rm int}(hkl)}{LPT}\right]^{1/2}. \tag{2.1.7.7}$$

Contrary to the situation with crystals of small compounds, it is not easy to find the phase angles $\alpha(hkl)$ for crystals of macromolecules by direct methods, although these methods are in a state of development (see Part 16). Indirect methods to determine the protein phase angles are:

(1) isomorphous replacement (see Part 12);
(2) molecular replacement (see Part 13);
(3) multiple-wavelength anomalous dispersion (MAD) (see Part 14).

From equation (2.1.7.5), it is clear that the reflections hkl and $\overline{hkl}$ have the same value for their structure-factor amplitudes, $|F(hkl)| = |F(\overline{hkl})|$, and for their intensities, $I(hkl) = I(\overline{hkl})$, but have opposite values for their phase angles, $\alpha(hkl) = -\alpha(\overline{hkl})$, assuming that anomalous dispersion can be neglected. Consequently, equation (2.1.7.6) reduces to

$$\rho(xyz) = (1/V) \sum_h \sum_k \sum_l |F(hkl)| \cos[2\pi(hx + ky + lz) - \alpha(hkl)] \tag{2.1.7.8}$$

or

$$\rho(xyz) = F(000)/V + (2/V) {\sum_h}' {\sum_k}' {\sum_l}' |F(hkl)| \times \cos[2\pi(hx + ky + lz) - \alpha(hkl)]. \tag{2.1.7.9}$$

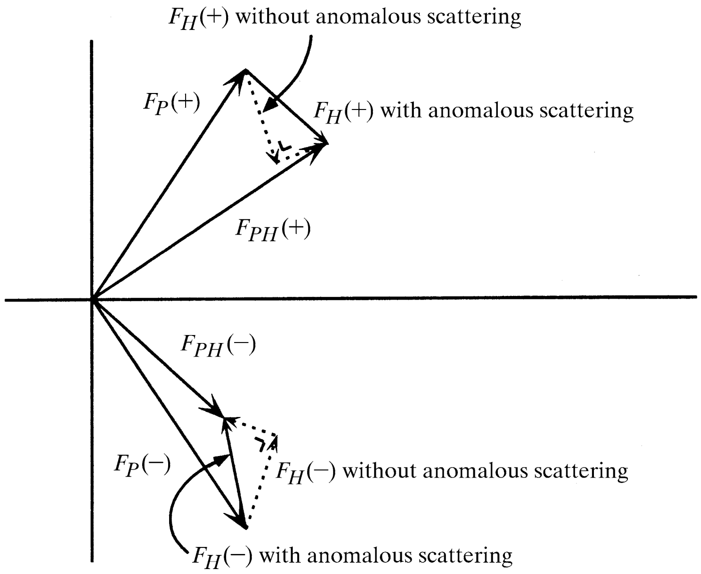
$\sum'$ denotes that $F(000)$ is excluded from the summation and that only the reflections hkl, and not $\overline{hkl}$, are considered.

The two reflections, hkl and $\overline{hkl}$, are called Friedel or Bijvoet pairs.

If anomalous dispersion cannot be neglected, the two members of a Friedel pair have different values for their structure-factor amplitudes, and their phase angles no longer have opposite values. This is caused by the f'' contribution to the anomalous scattering (Fig. 2.1.7.1). Macromolecular crystals show anomalous dispersion if the structure contains, besides the light atoms, one or more heavier atoms. These can be present in the native structure or are introduced in the isomorphous replacement technique or in MAD analysis.

2.1.8. Symmetry in the diffraction pattern

In the previous section, it was noted that $I(hkl) = I(\overline{hkl})$ if anomalous scattering can be neglected. In this case, the effect is that the diffraction pattern has a centre of symmetry. This is also true for the reciprocal lattice if the reciprocal-lattice points (hkl) are weighted with their $I(hkl)$ values. If the crystal structure has symmetry elements, they are also found in the diffraction pattern and in the weighted reciprocal lattice. Macromolecular crystals of biological origin are enantiomorphic and the symmetry operators in the crystal are restricted to rotation axes and screw axes. It is evident that a rotation of the real lattice will cause the same



$F_H(+)$ without anomalous scattering
$F_P(+)$
$F_H(+)$ with anomalous scattering
$F_{PH}(+)$
$F_{PH}(-)$
$F_P(-)$
$F_H(-)$ without anomalous scattering
$F_H(-)$ with anomalous scattering

Figure 2.1.7.1
An Argand diagram for the structure factors of the two members of a Friedel pair. (+) represents *hkl* and (−) represents $\overline{hkl}$. F_P is the contribution to the structure factor by the non-anomalously scattering protein atoms and F_H is that for the anomalously scattering atoms. F_H consists of a real part with an imaginary part perpendicular to it. The real parts are mirror images with respect to the horizontal axis. The imaginary parts are rotated counterclockwise with respect to the real parts (Section 2.1.4.4). The result is that the total structure factors, $F_{PH}(+)$ and $F_{PH}(-)$, have different amplitudes and phase angles. Reproduced with permission from Drenth (1999). Copyright (1999) Springer-Verlag.

rotation of the reciprocal lattice. If this rotation is the result of a symmetry operation around an axis, the crystal structure looks exactly the same as before the rotation, and the same must be true for the weighted reciprocal lattice. However, screw axes in the crystal lattice reduce to normal (non-screw) rotation axes in the weighted reciprocal lattice, as has been shown by Waser (1955). We follow his arguments, but must first introduce matrix notation for convenience.

If **r** is a position vector and **h** a vector in reciprocal space, the scalar product

$$\mathbf{h}\cdot\mathbf{r} = (h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*)\cdot(\mathbf{a}x + \mathbf{b}y + \mathbf{c}z) = hx + ky + lz,$$

or in matrix notation,

$$(hkl)\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \mathbf{h}^T\mathbf{r},$$

where $(hkl) = \mathbf{h}^T$ is a row vector and

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} = \mathbf{r}$$

is a column vector. $\mathbf{h}^T$ is the transpose of column vector **h** (rows and columns are interchanged). In this notation, the structure factor is given by

$$F(\mathbf{h}) = \int_{\text{cell}} \rho(\mathbf{r})\exp(2\pi i\mathbf{h}^T\cdot\mathbf{r})\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.1)$$

The symmetry operation of a screw axis is a combination of a rotation and a translation. The rotation can be represented by the matrix **R** and the translation by the vector **t**. Because of the screw-axis symmetry, $\rho(\mathbf{R}\cdot\mathbf{r}+\mathbf{t}) = \rho(\mathbf{r})$.

$F(\mathbf{h})$ can also be expressed as

$$\begin{aligned} F(\mathbf{h}) &= \int_{\text{cell}} \rho(\mathbf{R}\cdot\mathbf{r}+\mathbf{t})\exp[2\pi i\mathbf{h}^T\cdot(\mathbf{R}\cdot\mathbf{r}+\mathbf{t})]\,\mathrm{d}v_{\text{real}} \\ &= \exp(2\pi i\mathbf{h}^T\cdot\mathbf{t})\int_{\text{cell}} \rho(\mathbf{r})\exp(2\pi i\mathbf{h}^T\cdot\mathbf{R}\cdot\mathbf{r})\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.2) \end{aligned}$$

Because $\mathbf{h}^T\cdot\mathbf{R} = (\mathbf{R}^T\cdot\mathbf{h})^T$, where $\mathbf{R}^T$ is the transpose of the matrix **R**, equation (2.1.8.2) can be written as

$$F(\mathbf{h}) = \exp(2\pi i\mathbf{h}^T\cdot\mathbf{t})\int_{\text{cell}} \rho(\mathbf{r})\exp[2\pi i(\mathbf{R}^T\cdot\mathbf{h})^T\cdot\mathbf{r}]\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.3)$$

By definition, the integral in equation (2.1.8.3) is $F\,(\mathbf{R}^T\cdot\mathbf{h})$, and, therefore

$$F(\mathbf{h}) = \exp(2\pi i\mathbf{h}^T\cdot\mathbf{t})F(\mathbf{R}^T\cdot\mathbf{h}).$$

Conclusion: The phase angles of the two structure factors are different for $\mathbf{t}\neq 0$:

$$\alpha(\mathbf{h}) = \alpha(\mathbf{R}^T\cdot\mathbf{h}) + 2\pi\mathbf{h}^T\cdot\mathbf{t}, \qquad (2.1.8.4)$$

but the structure-factor amplitudes and, therefore, the intensities are always equal:

$$I(\mathbf{h}) = I(\mathbf{R}^T\cdot\mathbf{h}) \quad\text{or}\quad I[(\mathbf{R}^T)^{-1}\cdot\mathbf{h}] = I(\mathbf{h}). \qquad (2.1.8.5)$$

The matrices $(\mathbf{R}^T)^{-1}$ in reciprocal space and **R** in direct space denote rotation over the same angle. Therefore, both an *n*-fold screw axis and an *n*-fold rotation axis in the crystal correspond to an *n*-fold axis in the weighted reciprocal lattice.

However, screw axes distinguish themselves from non-screw axes by extinction of some reflections along the line in reciprocal space corresponding to the screw-axis direction. This will be shown for a twofold screw axis along the monoclinic *b* axis.

The electron density at **r**, $\rho(\mathbf{r})$, is then equal to the electron density at $\mathbf{R}\cdot\mathbf{r}+\mathbf{t}$, where $\mathbf{R}\cdot\mathbf{r}$ is a rotation that leaves the value of the *y* coordinate unchanged. **t** is equal to **b**/2.

$$F(\mathbf{h}) = \int_{\text{half the cell}} \rho(\mathbf{r})\{\exp(2\pi i\mathbf{h}^T\cdot\mathbf{r}) + \exp[2\pi i\mathbf{h}^T(\mathbf{R}\cdot\mathbf{r}+\mathbf{t})]\}\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.6)$$

For the (0*k*0) reflections, (**h** along $\mathbf{b}^*$) is $\mathbf{h} = k\mathbf{b}^*$, giving

$$\mathbf{h}^T\cdot\mathbf{r} = \mathbf{h}^T\cdot\mathbf{R}\cdot\mathbf{r} = 0 + ky + 0 \text{ and } \mathbf{h}^T\cdot\mathbf{t} = k/2.$$

This simplifies equation (2.1.8.6) to

$$F(0k0) = [1+\exp(\pi ik)]\int_{\text{half the cell}} \rho(\mathbf{r})\exp(2\pi iky)\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.7)$$

If *k* is odd, $F(0k0) = 0$, because $1+\exp(\pi ik) = 0$.

This type of systematic absence, due to screw components in the symmetry elements, occurs along lines in reciprocal space. Other types of absence apply to all *hkl* reflections. They result from the centring of the unit cell (Fig. 2.1.1.4). Suppose the unit cell is centred in the *ab* plane (*C* centring). Consequently, the electron density at **r** is equal to the electron density at $\mathbf{r}+\mathbf{t}$, with $\mathbf{t} = \mathbf{a}/2 + \mathbf{b}/2$ and $\mathbf{h}^T\cdot\mathbf{t} = h/2 + k/2$. The structure factor can then be written as

$$F(\mathbf{h}) = \{1+\exp[\pi i(h+k)]\}\int_{\text{half the cell}} \rho(\mathbf{r})\exp\big(2\pi i\mathbf{h}^T\cdot\mathbf{r}\big)\,\mathrm{d}v_{\text{real}}. \qquad (2.1.8.8)$$

The conclusion is that when $(h+k)$ is odd, the structure factors are zero and no diffracted intensity is observed for those reflections.

2.1.9. The Patterson function

In 1934, A. L. Patterson presented a method for locating the atomic positions in not too complicated molecules without knowledge of the phase angles (Patterson, 1934). The method involves the calculation of the Patterson function, $P(uvw) = P(\mathbf{u})$:

$$P(\mathbf{u}) = (1/V)\sum_{\mathbf{h}} |F(\mathbf{h})|^2 \cos(2\pi\mathbf{h}\cdot\mathbf{u}), \qquad (2.1.9.1)$$

or, written as an exponential function,

$$P(\mathbf{u}) = (1/V)\sum_{\mathbf{h}} |F(\mathbf{h})|^2 \exp(2\pi i\mathbf{h}\cdot\mathbf{u}). \qquad (2.1.9.2)$$

Equations (2.1.9.1) and (2.1.9.2) give the same result, because in the definition of $P(\mathbf{u})$ anomalous dispersion is neglected, resulting in $|F(\mathbf{h})|^2 = |F(-\mathbf{h})|^2$. Comparison with equations (2.1.7.3) and (2.1.7.6) shows that the Patterson function $P(\mathbf{u})$ is a Fourier summation with coefficients $|F(\mathbf{h})|^2$ instead of $F(\mathbf{h}) = |F(\mathbf{h})|\exp[i\alpha(\mathbf{h})]$. The periodicity, and thus the unit cell, are the same for the electron density and the Patterson function. For the Patterson function, many authors prefer to use **u** rather than **r** as the position vector.

The fundamental advantage of Patterson's discovery is that, in contrast to the calculation of $\rho(\mathbf{r})$, no phase information is needed for calculating $P(\mathbf{u})$.

The Patterson map can be obtained directly after the intensities of the reflections have been measured and corrected. However, what kind of information does it provide? This can be understood from an alternative expression for the Patterson function:

$$P(\mathbf{u}) = \int_{\mathbf{r}} \rho(\mathbf{r})\rho(\mathbf{r}+\mathbf{u})\,\mathrm{d}v_{\text{real}}. \qquad (2.1.9.3)$$

Equation (2.1.9.3) leads to the same result as equation (2.1.9.1), as can be proved easily by substituting expression (2.1.7.3) for ρ in the right-hand side of equation (2.1.9.3).

On the right-hand side of the equation, the electron density $\rho(\mathbf{r})$ at position **r** in the unit cell is multiplied by the electron density $\rho(\mathbf{r}+\mathbf{u})$ at position $\mathbf{r}+\mathbf{u}$; the integration is over all vectors **r** in the unit cell. The result of the integration is that the Patterson map will show peaks at the end of vectors **u** between atoms in the unit cell of the structure; all these Patterson vectors start at the origin of the Patterson cell. This can best be understood with a simple example. In Fig. 2.1.9.1, a two-dimensional unit cell is drawn containing only two atoms (1 and 2). To calculate the Patterson map, a vector **u** must be moved through this cell, and, according to equation (2.1.9.3), for every position and orientation of **u**, the electron densities at the beginning and at the end of **u** must be multiplied. It is clear that this product will generally be zero unless the length and the orientation of **u** are such that it begins in atom 1 and ends in atom 2, or the other way around. If so, there is a peak in the Patterson map at the end of vector **u** and at the end of vector $-\mathbf{u}$, implying that the Patterson map is always centrosymmetric. The origin itself, where vector $\mathbf{u} = 0$, always has a high peak because

$$P(\mathbf{u}=0) = \int_{\mathbf{r}} \rho(\mathbf{r})\rho(\mathbf{r})\,\mathrm{d}v_{\text{real}} = \sum_{\mathbf{h}} |F(\mathbf{h})|^2.$$

The origin peak is equal to the sum of the squared local electron densities. The height of each non-origin peak is proportional to the product of $\rho(\mathbf{r})$ and $\rho(\mathbf{r}+\mathbf{u})$. This is an important feature in the isomorphous replacement method for protein-structure determination, in which the heavy-atom positions are derived from a difference Patterson calculated with coefficients $(|F_{PH}| - |F_P|)^2$, where $|F_{PH}|$ is the structure-factor amplitude of the heavy-atom derivative and $|F_P|$ is that of the native protein (see Part 12). The vectors between the heavy atoms are the most prominent features in such a map.

The number of peaks in a Patterson map increases much faster than the number of atoms. For n atoms in the real unit cell, there are n^2 Patterson peaks, n of them superimposed at the origin, and $n \times (n-1)$ elsewhere in the Patterson cell. Because the atomic electron densities cover a certain region and the width of a Patterson peak at **u** is roughly the sum of the widths of the atoms connected by **u**, overlap of peaks is a real problem in the interpretation of a Patterson map. It can almost only be done for unit cells with a restricted number of atoms unless some extra information is available. For crystals of macromolecules, it is certainly impossible to derive the structure from an interpretation of the Patterson map.

The situation can be improved through sharpening the Patterson peaks by simulating the atoms as point scatterers. This can be achieved by replacing the $|F(\mathbf{h})|^2$ values with modified intensities which, on average, do not decrease with $\sin\theta/\lambda$. For instance, suitable intensities for this purpose are the squared normalized structure-factor amplitudes $|E(\mathbf{h})|^2$ (Section 2.1.4.6), the average of which is 1 at all $\sin\theta/\lambda$. A disadvantage of sharpening to point peaks is the occurrence of diffraction ripples around the sharp peaks, induced by truncation of the Fourier series in equation (2.1.9.1). Therefore, modified intensities corresponding to less sharpened peaks are sometimes used [*IT* B (2008), Chapter 2.3, pp. 245–246]. Diffraction ripples that seriously disturb the Patterson map are generated by the high origin peak, and, particularly for sharpened maps, it is advisable to remove this peak. This implies that $P(\mathbf{u}=0) = 0$ [equation (2.1.9.1)]. It is easy to verify that this requires coefficients $[|F(\mathbf{h})|^2 - \langle|F(\mathbf{h})|^2\rangle]$ for the $|F(\mathbf{h})|^2$ map and $[|E(\mathbf{h})|^2 - 1]$ for the $|E(\mathbf{h})|^2$ map. Note that the term for $\mathbf{h} = 0$ is omitted and that the average of $|F(\mathbf{h})|^2$ must be taken for the appropriate $\sin\theta/\lambda$ region.

The symmetry in a Patterson map is related to the symmetry in the electron-density map, but it is not necessarily the same. For instance, screw axes in the real cell become non-screw axes in the Patterson cell, because all interatomic vectors start at the origin. It is possible, however, to distinguish between screw axes and non-screw axes by the concentration of peaks in the Patterson map. For instance, the consequence of a twofold symmetry axis along **b** is the presence of a large number of peaks in the $(u0w)$ plane of the Patterson map. For a screw axis with translation $\frac{1}{2}$ along **b**, the peaks lie in the $(u\frac{1}{2}w)$ plane. Such planes are called Harker planes (Harker, 1936). Peaks in Harker planes usually form the start of the interpretation of a Patterson map. Harker lines result from mirror planes, which do not occur in macromolecular crystal structures of biological origin.

Despite the improvements that can be made to the Patterson function, for structures containing atoms of nearly equal weight its complete interpretation can only be achieved for a restricted number of atoms per cell unless some extra information is available. Nowadays, most structure determinations of small compounds are based on direct methods for phase determination. However, these may fail for structures showing strong regularity. In these cases, Patterson interpretation is used as an alternative tool, sometimes in combination with direct methods. It is interesting to see that the value of the Patterson function has shifted from the small-compound field to macromolecular crystallography, where it plays an extremely useful role:

(1) in the isomorphous replacement method, the positions of the very limited number of heavy atoms attached to the macromolecule can be derived from a difference Patterson map, as mentioned earlier in this section;

(2) anomalous scatterers can be located by calculating a Patterson map with coefficients $[|F_{PH}(\mathbf{h})| - |F_{PH}(-\mathbf{h})|]^2$, in which $|F_{PH}(\mathbf{h})|$ is the structure-factor amplitude of the protein containing the anomalous scatterer;

(3) molecular replacement is based on the property that the Patterson map is a map of vectors between atoms in the real structure, combined with the fact that such a vector map is (apart from a rotation) similar for two homologous structures: the unknown and a known model structure.

I am greatly indebted to Aafje Looyenga-Vos for critically reading the manuscript and for many useful suggestions.

Chapter 2.2. Quality indicators in macromolecular crystallography: definitions and applications

H. M. Einspahr and M. S. Weiss

2.2.1. Introduction

The genesis of this chapter was a perceived need for a single location in the volume in which consensus definitions could be found for the many statistical indicators of quality or figures of merit that have been developed to monitor a macromolecular crystallography (MX) experiment and its final outcome, a model. The evolving experiment has generated a rich collection of *R* values, signal-to-noise indicators, correlation coefficients and other figures of merit. As improvements in data collection, processing and other aspects of the experiment continue, we can expect a continued evolution of new or improved indicators of quality with which to monitor the impact of those improvements.

This chapter, then, attempts to provide a comprehensive list of the indicators of quality currently in use and, for each indicator in the list, a precise definition that conforms to consensus interpretations of the literature and current practice. The authors acknowledge that useful indicators may have been missed in the sweep that produced this list, but hasten to point out that the generation of new indicators is an ongoing process with the newest ones often in obscurity for a period before their utility is recognized and adopted by experimenters. There is also a subset of the indicators in the list whose members stand out as universally accepted and crucial indicators that either every experimental description must include or that every experimenter should be familiar with. A summary of these is given at the end of this article in Table 2.2.11.1. The authors also acknowledge that there may be competing definitions for some indicators. Where they occur, these competing definitions will be pointed out and a discussion will be provided which, at a minimum, will attempt to clarify the differences, but will also, where possible, attempt to arbitrate or discriminate among opposing views. It should be noted that the scope of this chapter is primarily concerned with the crystallographic experiment. While quality indicators useful for model refinement are given in Sections 2.2.8 to 2.2.10, the validation of the refined model is covered more extensively in Part 21 of this volume.

Before proceeding with the quality indicators themselves, it is necessary to discuss a small collection of parameters whose values, typically left to the experimenter to fix, impact on virtually all the indicators of quality we present here. The reason for this wide impact is that they are used to determine which reflections are included in the final data set in question. In their simplest form, the effect is a limit, applied as a cutoff in intensity or resolution, beyond which reflections are excluded from consideration.

When a cutoff is applied based on intensities, the limiting value may be simply a fixed number, for example zero, or it may vary from reflection to reflection, for example some multiple of the standard uncertainty of the reflection intensity. Reflections with intensities below limiting values are excluded. Reflections excluded in this manner are often referred to as unobserved.

When the objective is to estimate electron-density distributions, the exclusion of intensity terms below very low limiting values is unlikely to have any significant negative impact and may offer a positive savings in computation time. This may not be the case, however, when the objective is refinement. Inclusion of reflections of low intensity, even zero, may have important positive results on the quality of the final model. True, some of these intensities may be poorly known or, if less than zero, physically unrealistic, but given the excellent quality of modern data-collection instrumentation and techniques, few intensities, if any, are without some reasonable estimate of their standard uncertainty, so that weighting procedures can be applied to modulate the impact of individual terms in the final result and judgments can be made about exclusion of intensity values that are truly improbable. With the application of proper weighting procedures, there seems to be little justification for exclusion of reflections from consideration based on intensity (except for the truly improbable mentioned above) when computing indicators of quality. As instrumentation and techniques continue to improve, this is a topic that merits continued attention and debate within the MX community in search of consensus best practices for handling weak reflections and for including them in estimators of quality.

While an acceptable estimate of the nominal resolution of a diffraction data set is widely considered to be a high-value indicator of data quality, assignment of a value to this limit is typically left to the experimenter and is thus prone to subjectivity. Some guidelines for estimation have emerged. One would set the nominal resolution based on the percentage of weak reflections above the limit so that reflections with intensities above that limit would be included. An example might be the resolution at which 70% of unique reflections have intensities above zero or above some multiple of their standard uncertainties. Another way to estimate the nominal resolution which has gained wide acceptance is based on the overall signal-to-noise value where, in its most popular expression, the limit value is the resolution at which the mean signal-to-noise ratio in the outer resolution shell falls to 2. Each of these estimation methods is susceptible to convolution with limits based on intensity leading to, for example, a limit set as the resolution at which the mean signal-to-noise ratio 'of observed reflections' falls to 2. The guidelines for estimating resolution limits – the methods to be applied, the constraining values such as 70% or 2, and the proper integration with limits applied based on intensity – also merit further attention and discussion by the MX community, the goal being definition of consensus best practices. We take this opportunity to suggest that the widely accepted estimate, the resolution at which the mean signal-to-noise in the outer resolution shell falls to 2, calculated without imposition of a cutoff in intensity, has much to recommend it. True, some susceptibility to subjectivity remains in the definition of resolution-shell ranges and limits, but the impact is minimal and hardly worth the effort. On the other hand, modifying the indicator to remove the shells so that the mean signal-to-noise ratio applied to all data above an appropriately adjusted limit value would extinguish that source of subjectivity.

When a cutoff is applied based on nominal resolution, then considerations similar to those for intensity-based cutoffs apply.

Copyright © 2012 International Union of Crystallography

If the objective is to estimate electron-density distributions, exclusion of large numbers of weak intensity terms beyond a limiting resolution is unlikely to be of any significant impact except, perhaps, a favourable one in computation time. If a sparse population of more intense reflections is also excluded, the effect may also be positive by reducing aberrations that might interfere with interpretation. If the objective is refinement, the benefit is less clear, except possibly in computation time. The cost for that may be the exclusion of a few more intense terms that provide positive guidance to refinement. Another positive effect of a sharply defined limiting resolution might be improved estimation of the spherical interference function where it is needed. It appears that, in practice, the consensus is that, in applying a cutoff, the exclusion of a few intense terms is at worst of negligible impact overall.

Because many imposed limits that exclude data are dependent on estimates of standard uncertainty, procedures for estimation of standard uncertainty need to be considered. As suggested earlier, a diffraction data set without a standard uncertainty for each intensity measurement is certainly the exception in current practice. The methods used by data-processing programs to estimate these standard uncertainties may be difficult, even impossible, to discern, but at core they must all be based on counting statistics. With the continuing trend toward data sets of high multiplicity (also referred to as redundancy), however, estimates of standard uncertainties are available from distributions of replicate measurements about means. Both of these estimates have value and express impacts of somewhat different sources of error. It would seem therefore that, where applicable, the best way to accommodate both would be to calculate weighted average values of individual intensities, where the weights are derived from the standard uncertainties from data processing, and then to estimate the standard uncertainties for the weighted averages by application of standard propagation-of-error procedures. This, finally, is the third area we highlight here that deserves focused discussion within the MX community with the objective of defining consensus best practices.

Little remains to be included in these introductory preliminaries. It should be understood that most of these indicators of quality may be cast in terms of either structure factors or intensities. We draw little attention to this as we define individual indicators, except that, where one of the two possibilities seems to dominate in usage, we tend to define that form alone. It is also true that many of these indicators have counterparts in which individual reflection terms are weighted. In current practice, these forms find little use in application to biological macromolecules and we ignore them here. Finally, many of these indicators may be expressed as fractions, that is, as numbers between one and zero. They are also often expressed in the percentage form, that is, as numbers between one hundred and zero. While we confine our use to the former here, we make no statement of preference.

The remainder of this chapter consists primarily of individual sections that reflect the various steps from the crystallographic data-collection experiment to the refinement of the final model. Relevant quality indicators and definitions are given for each of the steps and the most commonly used are collected in Table 2.2.11.1.

2.2.2. Quality indicators for diffraction data

Once useful crystalline samples have been obtained, the collection of X-ray diffraction data is the next (and the last) experimental step in a structure determination. Although the greatest care may be taken to collect data of as high quality as possible, there remain circumstances and influences that limit the quality of the data. Over time, many indicators have been defined to describe various aspects of diffraction data quality. The most important ones are discussed here.

Nominal resolution, $d_{\min}$. The resolution of a diffraction data set describes the extent of measurable data and is calculated by Bragg's law [equation (2.2.2.1)] based on the maximum Bragg angle 2θ included in the data set for a given data-collection wavelength λ. As discussed above, the nominal resolution is a limit set by the experimenters and is well known to be prone to subjective judgment. A number of suggestions have been made to reduce the subjectivity associated with this limit. One defines the limit as the resolution within which the intensities of a fraction of the unique reflections, for example 70%, are above a threshold, for example zero or three times their standard uncertainties. Another suggested limiting criterion, discussed further below, recommends that the nominal resolution be set as the midpoint of the resolution range of the shell at which the mean signal-to-noise ratio falls below 2.

$$d_{\min} = \lambda / 2 \sin \theta. \qquad (2.2.2.1)$$

True resolution, $d_{\rm true}$. The true resolution of a diffraction data set is defined as the minimum distance between two objects in a crystal that permits their images in the resultant electron-density map to be resolved. Often, $d_{\rm true}$ is approximated as $d_{\min}$.

To illustrate this crucial distance, represent two equivalent atoms by equal overlapping Gaussians. One might then consider that the distance between them that just permits distinguishing them as individual atoms might be the distance at which the electron-density value at the midpoint between the atoms drops to a value just below that at the positions of the atoms. For a normal distribution, this distance is 2σ, twice the standard deviation of the distribution.

Another perspective is provided by the realization that, when a Fourier synthesis is terminated at a resolution cutoff $d_{\min}$, successive spheres of negative and positive density of decreasing amplitude surround the maxima of positive density at atomic positions in that synthesis. It has been shown that the distance from the centre of such a maximum to the first zero is $0.715d_{\min}$ (James, 1948), which is a useful estimate of the limiting distance between distinguishable features in the electron-density map or $d_{\rm true}$. Similar estimates are used in other areas, notably for defining resolution in astronomy. A more recent re-evaluation suggests that a limit of $0.917d_{\min}$ is a better value, especially when the effects of form factors and atomic displacement parameters are considered (Stenkamp & Jensen, 1984). Add to that the effects of errors in experimental amplitudes and derived phases, and the approximation of $d_{\rm true}$ as $d_{\min}$ seems quite reasonable.

Optical resolution, $d_{\rm opt}$. The optical resolution $d_{\rm opt}$ is calculated from the standard deviation of a Gaussian fitted to the origin peak of the Patterson function ($\sigma_{\rm Patt}$) of the diffraction data set and the standard deviation of another Gaussian fitted to the origin peak of the spherical interference function ($\sigma_{\rm sph}$). This definition is based on Vaguine *et al.* (1999) and is implemented in the program *SFCHECK*. The optical resolution is intended to account for uncertainties in the data, atomic displacement factors, effects of crystal quality and series-termination effects by means of a propagation-of-error-like approach (Blundell & Johnson, 1976; Vaguine *et al.*, 1999). It has been suggested that $d_{\rm opt}$ is a better approximation of $d_{\rm true}$ than

d_{min} (Weiss, 2001).

$$d_{\mathrm{opt}} = [2(\sigma^2_{\mathrm{Patt}} + \sigma^2_{\mathrm{sph}})]^{1/2}. \qquad (2.2.2.2)$$

Completeness, *C*. The completeness *C* of a diffraction data set is defined as the fraction of the unique reflections in a given space group to a given nominal resolution d_{min} that have been measured at least once during data collection. *C* may be given assuming that Friedel symmetry is either applied or not. In the latter case, *C* is also referred to as anomalous completeness. In the program *SCALA* (Evans, 2006), the anomalous completeness is defined based on acentric reflections only.

Effective resolution, d_{eff}. Since any missing reflection of a data set leads to a deterioration of the model parameters (Hirshfeld & Rabinovich, 1973; Arnberg *et al.*, 1979), an effective resolution may be defined based on the nominal resolution d_{min} and the cube root of the completeness *C* of the data set.

$$d_{\mathrm{eff}} = d_{\mathrm{min}} C^{-1/3}. \qquad (2.2.2.3)$$

Multiplicity (or redundancy), *N*. The multiplicity or redundancy *N* of a diffraction data set defines on average how many times a reflection *hkl* has been observed during the data-collection experiment including symmetry mates and replicate measurements. *N* may be given assuming that Friedel symmetry is either applied or not.

Merging *R* factor, R_{merge}. The merging *R* factor of a diffraction data set describes the spread of the individual intensity measurements I_i of a reflection *hkl* around the mean intensity $\langle I(hkl)\rangle$ of this reflection. Sometimes R_{merge} is also referred to as *R* factor (observed) (in the program *XDS*; Kabsch, 1988, 1993, 2010; Chapter 11.6), as R_{sym} or as R_{linear} (in the program *SCALEPACK*; Otwinowski & Minor, 1997). In fractional form, this is

$$R_{\mathrm{merge}} = \sum_{hkl}\sum_{i} |I_i(hkl) - \langle I(hkl)\rangle| / \sum_{hkl}\sum_{i} I_i(hkl), \qquad (2.2.2.4)$$

where $\langle I(hkl)\rangle$ is the mean of the several individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*. The sums $\sum_{hkl}$ and $\sum_i$ run over all observed unique reflections *hkl* and over all individual observations *i* of a given reflection *hkl*. It should be noted that alternative definitions of R_{merge} exist. In one, $I_i(hkl)$ in the denominator is replaced by $\langle I(hkl)\rangle$, thereby producing an expression that is formally equivalent to the one above. In another, $I_i(hkl)$ in the denominator is replaced by $|I_i(hkl)|$ with the suggestion that the denominator is thereby prevented from becoming negative or zero, even in the case of many negative-intensity observations. One should note, however, the counter-intuitive side effect: artificial damping of R_{merge} values, that is, reducing expected higher R_{merge} values of data sets with more weak reflections.

The usefulness of R_{merge} as a quality indicator for diffraction data is limited because it is dependent on the multiplicity of a data set (Diederichs & Karplus, 1997*a*,*b*; Weiss & Hilgenfeld, 1997; Weiss, 2001). The higher the multiplicity of a data set, the higher its R_{merge} will be, although, based on statistics, the better determined the averaged intensity values should be. Despite these shortcomings, R_{merge} is still widely used today.

Redundancy-independent merging *R* factor, $R_{\mathrm{r.i.m.}}$ or R_{meas}. The redundancy-independent merging *R* factor $R_{\mathrm{r.i.m.}}$ or R_{meas} describes the precision of the individual intensity measurements I_i, independent of how often a given reflection has been measured. Because of its independence of the redundancy (hence its name), it has been proposed that $R_{\mathrm{r.i.m.}}$ or R_{meas} should be used as a substitute for the conventional R_{merge} (Diederichs & Karplus, 1997*a*,*b*; Weiss & Hilgenfeld, 1997; Weiss, 2001). In fractional form, this is

$$R_{\mathrm{r.i.m.}} = \sum_{hkl}\{N(hkl)/[N(hkl)-1]\}^{1/2} \times \sum_{i} |I_i(hkl) - \langle I(hkl)\rangle| / \sum_{hkl}\sum_{i} I_i(hkl), \qquad (2.2.2.5)$$

where $\langle I(hkl)\rangle$ is the mean of the $N(hkl)$ individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*. As for R_{merge}, the sums $\sum_{hkl}$ and $\sum_i$ run over all observed unique reflections *hkl* and over all individual observations *i* of a given reflection *hkl*.

Precision-indicating merging *R* factor, $R_{\mathrm{p.i.m.}}$. The precision-indicating merging *R* factor $R_{\mathrm{p.i.m.}}$ describes the precision of the averaged intensity measurements $\langle I(hkl)\rangle$ (Weiss, 2001). In fractional form, this is

$$R_{\mathrm{p.i.m.}} = \sum_{hkl}\{1/[N(hkl)-1]\}^{1/2} \times \sum_{i} |I_i(hkl) - \langle I(hkl)\rangle| / \sum_{hkl}\sum_{i} I_i(hkl), \qquad (2.2.2.6)$$

where $\langle I(hkl)\rangle$ is the mean of the $N(hkl)$ individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*. As with R_{merge} and $R_{\mathrm{r.i.m.}}$ or R_{meas}, the sums $\sum_{hkl}$ and $\sum_i$ run over all observed unique reflections *hkl* and over all individual observations *i* of a given reflection *hkl*.

***R* factor of merged intensities or amplitudes, $R_{\mathrm{mrgd}\text{-}I}$ and $R_{\mathrm{mrgd}\text{-}F}$.** An alternative precision-indicating merging *R* factor, called R_{mrgd}, is defined as the *R* factor between two or more data sets or between two subsets of a data set created by randomly apportioning the individual intensity measurements between the two subsets (Diederichs & Karplus, 1997*a*,*b*). R_{mrgd} can be calculated for intensities ($R_{\mathrm{mrgd}\text{-}I}$) or structure-factor amplitudes ($R_{\mathrm{mrgd}\text{-}F}$). The latter quantity was suggested to present a lower limit for the crystallographic *R* factor of a model against the observed data (Diederichs & Karplus, 1997*a*,*b*). In fractional form

$$R_{\mathrm{mrgd}\text{-}I} = 2\sum_{hkl} |\langle I_1(hkl)\rangle - \langle I_2(hkl)\rangle| / \sum_{hkl}\langle I_1(hkl)\rangle + \langle I_2(hkl)\rangle, \qquad (2.2.2.7)$$

where $\langle I_1(hkl)\rangle$ and $\langle I_2(hkl)\rangle$ are the mean intensity values for the individual observations of the reflections *hkl*, which have been partitioned into the two subsets 1 and 2. The sums $\sum_{hkl}$ run over all observed unique reflections. $R_{\mathrm{mrgd}\text{-}I}$ is related to $R_{\mathrm{p.i.m.}}$ by a constant factor ($R_{\mathrm{mrgd}\text{-}I} = 2^{1/2} R_{\mathrm{p.i.m.}}$).

$R_{\mathrm{mrgd}\text{-}F}$ is defined analogously to $R_{\mathrm{mrgd}\text{-}I}$ (Diederichs & Karplus, 1997*a*,*b*). In the equation, only the intensities are replaced by structure-factor amplitudes.

$$R_{\mathrm{mrgd}\text{-}F} = 2\sum_{hkl} |\langle F_1(hkl)\rangle - \langle F_2(hkl)\rangle| / \sum_{hkl}\langle F_1(hkl)\rangle + \langle F_2(hkl)\rangle. \qquad (2.2.2.8)$$

In order to cope with negative-intensity observations, pseudo-amplitudes had to be introduced just for the purpose of calculating $R_{\mathrm{mrgd}\text{-}F}$ ($F = I^{1/2}$ if $I \geq 0$ and $F = -|I|^{1/2}$ if $I < 0$).

Note. The approach of comparing randomly partitioned subsets of a given data set is used for a variety of quality indicators. While there is potential for variation in these indicators from one partitioning of the data set to another, an average of several random partitionings should be expected to give a useful estimate. There is also potential for subjectivity, but the principal value of these indicators is to assist the experimenter in proper analysis and they are less often applied to compare experiments from different laboratories and are seldom published.

Pooled coefficient of variation, PCV. The pooled coefficient of variation PCV is the ratio of the sum of the standard deviations to the sum of the reflection intensities (Diederichs & Karplus, 1997*a*,*b*). PCV is related to $R_{\rm meas}$ or $R_{\rm r.i.m.}$ by the factor $(\pi/2)^{1/2}$. In fractional form, this is

$$\mathrm{PCV} = \frac{\sum_{hkl}\left(\{1/[N(hkl)-1]\}^{1/2}\sum_i |I_i(hkl)-\langle I(hkl)\rangle|^2\right)^{1/2}}{\sum_{hkl}\sum_i I_i(hkl)}, \tag{2.2.2.9}$$

where $\langle I(hkl)\rangle$ is the mean of the $N(hkl)$ individual measurements $I_i(hkl)$ of the intensity of reflection hkl.

Mean signal-to-noise ratio, ⟨*I*/σ(*I*)⟩. The signal-to-noise ratio $I_i/\sigma(I_i)$ of an individual intensity measurement describes the statistical significance of a measured intensity. As a measure of the overall quality of a data set, the mean signal-to-noise ratio for all reflections is useful as an indication of the robustness of the data, that is, the average intensity as a multiple of the standard uncertainty. In addition, as mentioned above, the mean signal-to-noise ratio for all reflections within the outer resolution shell can be used to define the nominal resolution of a data set. For the data set as a whole or for a resolution shell of that data set, the mean signal-to-noise ratio, $\langle I/\sigma(I)\rangle$, is the sum of the signal-to-noise ratios of all individual reflections hkl within resolution limits divided by the number of individual reflections hkl within those resolution limits.

In principle there are two ways to define a mean signal-to-noise ratio of a data set (or a given resolution shell). The two ways yield different quantities, although, unfortunately, they are both called the mean signal-to-noise ratio. They differ in the manner in which mean signal-to-noise ratios of individual reflections hkl are calculated.

(i) $\langle I(hkl)\rangle/\sigma[I(hkl)]$. The mean signal-to-noise ratio of individual reflections hkl may be calculated as the ratio of the mean intensity $\langle I(hkl)\rangle$ and the r.m.s. scatter of $I_i(hkl)$ about that mean. This is a measure of the average significance of individual observations, but it does not take into account the multiplicity or redundancy of the measurements.

$$\begin{aligned}&\langle I(hkl)\rangle/\sigma[I(hkl)]\\ &\quad= \langle I(hkl)\rangle/[(1/N)\sum_i |I_i(hkl)-\langle I(hkl)\rangle|^2]^{1/2}.\end{aligned} \tag{2.2.2.10}$$

In the program *SCALA* (Evans, 2006), this value is reported as I/sigma.

(ii) $\langle I(hkl)\rangle/\sigma\langle I(hkl)\rangle$. $\langle I(hkl)\rangle$ is the average over all observations of the reflection hkl, and is sometimes weighted. $\sigma\langle I(hkl)\rangle$ is the propagation-of-error combination of standard uncertainties assigned at data processing for the individual measurements $I_i(hkl)$, that is, a modification of equation (2.2.2.10) in which the term $|I_i(hkl)-\langle I(hkl)\rangle|$ in the denominator is replaced by $\sigma_i(hkl)$, the experimental standard uncertainty for the measurement $I_i(hkl)$.

$$\langle I(hkl)\rangle/\sigma\langle I(hkl)\rangle = \langle I(hkl)\rangle/[(1/N)\sum_i \sigma_i(hkl)^2]^{1/2}. \tag{2.2.2.11}$$

An error model[1] is often applied in the denominator here to scale to the r.m.s. scatter in (i) above. In the program *SCALA* (Evans, 2006), this value is reported as Mn(I)/sd.

Both methods of defining the mean signal-to-noise ratio for the reflection hkl have merit. As suggested for individual intensities in Section 2.2.1, perhaps the best approach would be to calculate weighted averages and weighted standard uncertainties of the $I(hkl)$ where weights are the experimental standard uncertainties $\sigma_i(hkl)$ for individual measurements $I_i(hkl)$.

Highest possible signal-to-noise ratio, *I*/σ(*I*)$_{\rm asymptotic}$. A relatively recent addition to the collection of diffraction-data quality indicators is the highest possible signal-to-noise ratio of a data set $I/\sigma(I)_{\rm asymptotic}$ or ISa (Diederichs, 2010). ISa is calculated from the parameters of the error model used for inflating the standard deviations of the reflections with an intensity-dependent term.[1] Since ISa is practically independent of counting statistics, it was suggested to be a good measure of instrument errors manifesting themselves in the data set, provided the crystal is close to ideal and radiation damage is negligible. Data sets with ISa values of 25 or greater are considered to be very good and amenable to straightforward structure determination, while data sets exhibiting ISa values of 15 or less are considered marginal at best. The calculation of ISa is implemented in *XDS* versions of December 2009 or later (Kabsch, 2010).

Anomalous *R* factor, *R*$_{\rm anom}$. The anomalous R factor $R_{\rm anom}$ describes the sum of the differences in intensities of Friedel-related reflections (hkl) and $(\bar{h}\bar{k}\bar{l})$ relative to the sum of their mean intensities. In fractional form, this is

$$R_{\rm anom} = \sum_{hkl} |I(hkl) - I(\bar{h}\bar{k}\bar{l})|/\sum_{hkl}\langle I(hkl)\rangle, \tag{2.2.2.12}$$

where, in this case, $\langle I(hkl)\rangle$ is the mean intensity of the Friedel mates of the reflections hkl, or $\frac{1}{2}[I(hkl)+I(\bar{h}\bar{k}\bar{l})]$. Here, the sums $\sum_{hkl}$ run over all unique reflections with one of the indices, typically h, greater than zero ($h > 0$) for which both Friedel mates have been observed at least once.

The ratio of $R_{\rm anom}$ to $R_{\rm p.i.m.}$ has been proposed as a possible indicator for the strength of the anomalous signal (Panjikar & Tucker, 2002).

Anomalous correlation coefficient, CC$_{\rm anom}$. The anomalous correlation coefficient CC$_{\rm anom}$ quantifies the linear dependence of observed anomalous differences in two diffraction data sets. These can be data sets, for example, collected at two different wavelengths in a MAD experiment. In cases where only one data set is available, two randomly partitioned half data sets can be created for comparison.

Note. The correlation coefficient referred to here and elsewhere in this chapter is invariably the Pearson linear correlation coefficient (Rodgers & Nicewander, 1988):

$$\mathrm{CC} = \sum(x-\langle x\rangle)(y-\langle y\rangle)\Big/\Big[\sum(x-\langle x\rangle)^2\sum(y-\langle y\rangle)^2\Big]^{1/2}, \tag{2.2.2.13}$$

with x and y being, in this case, the anomalous differences $[I(hkl) - I(\bar{h}\bar{k}\bar{l})]$ or $[F(hkl) - F(\bar{h}\bar{k}\bar{l})]$ in the two data sets, $\langle x\rangle$ and $\langle y\rangle$ are their averages, and the summations are over all reflections

---

[1] Typically, the experimental standard uncertainties are modified by various correction factors in order to account for errors in the data that arise from other sources than counting statistics. The inflation factors are applied in various ways in different programs. In *SCALA* (Collaborative Computational Project, Number 4, 1994; Evans, 2006) they are called SDFAC, SDB and SDADD. In *SCALEPACK* (Otwinowski & Minor, 1997), they are called ERROR SCALE FACTOR and ESTIMATED ERROR. In *D*TREK* (Pflugrath, 1999), they are called E$_{\rm mul}$ and E$_{\rm add}$. In *XDS* (Kabsch, 1988, 1993, 2010; Chapter 11.6) they are called a and b.

hkl for which observations exist in both data sets across the entire resolution range or within a particular resolution shell. $\mathrm{CC}_{\mathrm{anom}}$ is a reliable indicator of the strength of the anomalous signal. Values above 0.30 are considered good.

R.m.s. correlation ratio. This is another statistic based on randomly partitioned data sets, which is calculated by the program *SCALA* (Evans, 2006; Collaborative Computational Project, Number 4, 1994). It is an analysis of the scatterplot of $[I_1(hkl) - I_1(\bar{h}\bar{k}\bar{l})]$ *versus* $[I_2(hkl) - I_2(\bar{h}\bar{k}\bar{l})]$, where the subscripts 1 and 2 identify the two half data sets. The analysis assumes that the correlation is ideally 1.0. The r.m.s. correlation ratio is defined as the ratio of the r.m.s. widths of the scatterplot distribution along the diagonal and perpendicular to the diagonal. This statistic seems to be more robust than $\mathrm{CC}_{\mathrm{anom}}$ to the presence of outliers. It cannot, however, be applied to analysing the correlations between different data sets.

Mean anomalous signal-to-noise ratio, $\langle d''/\sigma(d'')\rangle$. The anomalous signal-to-noise ratio of an individual reflection measurement $d''(hkl)/\sigma[d''(hkl)]$ is defined as the ratio of the observed anomalous intensity difference $d'' = |I(hkl) - I(\bar{h}\bar{k}\bar{l})|$ and the corresponding estimated standard uncertainty $\sigma(d'')$ in the measurement of this anomalous difference. The average of the anomalous signal-to-noise ratios for all reflections within a certain resolution range is used as an indicator of utility for phasing. A value of $(2/\pi)^{1/2} \simeq 0.8$ for mean $d''/\sigma(d'')$ of a resolution shell, for example, is taken to indicate that no anomalous signal is present (G. Sheldrick & G. Bunkoczi, personal communication).

Decay *R* factor, R_d. The decay *R* factor R_d is defined as a pairwise *R* factor based on the intensities of symmetry-related reflections occurring on different diffraction images (Diederichs, 2006). An increase in R_d as a function of difference in image-collection times is a good indicator of radiation damage occurring during data collection. In fractional form, this is

$$R_d = 2\sum_{hkl}\sum_{m-n}|I_m(hkl) - I_n(hkl)|/\sum_{hkl}\sum_{i}[I_m(hkl) + I_n(hkl)], \tag{2.2.2.14}$$

where $I_m(hkl)$ and $I_n(hkl)$ are the intensities of the reflection *hkl* occurring on images *m* and *n*. The only program in which this is currently implemented is *XDSSTAT*.

Wilson-plot *B* factor, B_{Wilson}. A Wilson plot (Wilson, 1949) is a plot for a contiguous series of resolution shells of the logarithm of the mean intensity in a given resolution shell divided by the sum of the squared atomic form factors for all atoms in the unit cell evaluated at the mean of the resolution limits of the shell. From a least-squares fit of a straight line to the linear part of the Wilson plot, the *B* factor B_{Wilson} can be derived. Typically, data of lower than 4.5 Å resolution are excluded from the fit. The more meaningful determinations of B_{Wilson} come from Wilson plots that are linear all the way to the nominal resolution $d_{\min}$ and minimize the occurrence of spikes due to ice rings.

$$\ln(\langle I_{\mathrm{obs}}\rangle/\sum_i f_i^2) = -\ln K_{\mathrm{Wilson}} - 2B_{\mathrm{Wilson}}/d^2, \tag{2.2.2.15}$$

where $\langle I_{\mathrm{obs}}(hkl)\rangle$ is the mean over the intensities of all observed reflections *hkl* in a given resolution shell. The sum $\sum_i$ runs over all atoms in the structure. The parameter *d* is the midpoint of the resolution shell over which I_{obs} has been averaged. K_{Wilson} is an absolute scale factor.

2.2.3. Comparing different diffraction data sets

In MX, there are many instances when two or more diffraction data sets have to be compared to each other. An important decision which has to be made is, for instance, whether data sets collected from different crystals are isomorphous enough so that they can be merged together. Another task is the comparison of a native data set and a heavy-atom derivative. The question here is how much of the observed difference is due to non-isomorphism and how much is due to isomorphous replacement.

Scaling *R* factor, R_{scale}. The scaling *R* factor R_{scale} between two data sets is defined as the difference in the structure-factor amplitudes of one data set relative to the structure-factor amplitudes of the other data set after the two data sets have been scaled to each other.

$$R_{\mathrm{scale}} = \sum_{hkl}|F_1 - F_2|/\sum_{hkl}|F_1|. \tag{2.2.3.1}$$

However, the above formula is asymmetric with respect to data sets 1 and 2. An alternative symmetric formula is

$$R_{\mathrm{scale}} = 2\sum_{hkl}|F_1 - F_2|/\sum_{hkl}(F_1 + F_2). \tag{2.2.3.2}$$

R_{scale} is also often given based on intensities rather than structure-factor amplitudes.

Gradient from a normal probability analysis. For each reflection *hkl* in two data sets that have been scaled to each other, the quantity $\Delta(\mathrm{real})$ is computed and compared with its expectation value $\Delta(\mathrm{expected})$ assuming a normal distribution of errors (Howell & Smith, 1992). If $\Delta(\mathrm{real})$ is plotted against $\Delta(\mathrm{expected})$, random differences between the two data sets give rise to a slope of 1.0. Significant differences result in slopes significantly larger than 1.0. Such an analysis is implemented in the program *SCALEIT* (Collaborative Computational Project, Number 4, 1994).

$$\Delta(\mathrm{real}) = (F_1 - F_2)/[\sigma(F_1)^2 + \sigma(F_2)^2]^{1/2}. \tag{2.2.3.3}$$

2.2.4. Quality indicators for substructure determination

The first step of a crystal structure determination after processing and analysing the diffraction data is to use the observed isomorphous and/or anomalous differences in order to determine the isomorphous or anomalous substructure. Since such substructures typically consist of rather few atoms, which are relatively far apart, direct-methods approaches have been adopted from small-molecule crystallography and have largely superseded pure Patterson-based methods. The most widely used computer programs for substructure determination are *SHELXD* (Schneider & Sheldrick, 2002; Sheldrick, 2008), *SnB* (Weeks *et al.*, 1993, 1994) and *HySS* (Grosse-Kunstleve & Adams, 2003).

Correlation coefficient CC(all). CC(all) measures the correlation of the *E* values (analogous to normalized structure factors; Hauptman & Karle, 1953) derived from the observed isomorphous or anomalous differences and those calculated from the substructure model. CC(all) is another application of the Pearson linear correlation coefficient [see equation (2.2.2.13)] and is calculated for all reflections. In the equation, *x* and *y* are the *E* values derived from the observed and calculated differences. CC(all) is typically used to assess the successful determination of the isomorphous or anomalous substructure in a macromolecule. A value of CC(all) ≥ 0.3 often indicates that the substructure has been correctly identified (Schneider & Sheldrick, 2002).

Correlation coefficient CC(weak). Like CC(all), CC(weak) is the Pearson linear correlation coefficient [see equation (2.2.2.13)] between the E values (analogous to normalized structure factors as above) derived from the observed isomorphous or anomalous differences and those calculated from the substructure model. In contrast to CC(all), however, CC(weak) is calculated for the weak reflections only. As above, x and y are the E values derived from the observed and calculated differences. The E-value cutoff for defining a reflection as weak can be chosen by the user, but a typical threshold value is 1.5, although lower values may be required for low-resolution data (Schneider & Sheldrick, 2002). A value of CC(weak) ≥ 0.15 often indicates that the substructure has been correctly identified (Sheldrick, 2010).

The minimal function, $R(\varphi)$. The minimal function $R(\varphi)$ is a measure of the mean-square difference between the values of the triplets calculated using a particular set of phases and the expected values of the same triplets as given by the ratio of modified Bessel functions. The minimal function is expected to have a constrained global minimum when the phases are equal to their correct values for some choice of origin and enantiomorph (the minimal principle).

$$R(\varphi) = \sum_{H,K} A_{HK}\left\{\cos\varphi_{HK} - [I_1(A_{HK})/I_0(A_{HK})]\right\}^2 \Big/ \sum_{H,K} A_{HK}, \tag{2.2.4.1}$$

where $A_{HK} = (2/N^{1/2})|E_H E_K E_{H+K}|$ with N being the number of atoms in the corresponding primitive unit cell. The minimal function is the function minimized in the program *Shake&Bake*, abbreviated as *SnB* (Weeks *et al.*, 1993, 1994).

2.2.5. Quality indicators for phase determination

Once the isomorphous or anomalous substructure has been successfully determined, it can be used as reference point for the calculation of phases. The quality of the resulting phases is dependent on the strength of the isomorphous or anomalous signal and the completeness and correctness of the isomorphous or anomalous substructure.

Cullis *R* factor, $R_{\rm Cullis}$. The Cullis R factor (Cullis *et al.*, 1961) for phase determination by isomorphous replacement is defined as the ratio between the lack-of-closure error $\varepsilon(\varphi_{\rm P})$ [equation (2.2.5.1*a*) below] and the isomorphous difference $|F_{\rm PH} - F_{\rm P}|$. It is the most useful signal for a usable heavy-atom derivative. Values < 0.6 for centrosymmetric data are excellent, while values < 0.9 are still usable.

$$\varepsilon(\varphi_{\rm P}) = \big|F_{\rm PH} - |F_{\rm P} + F_{\rm H}|\big|, \tag{2.2.5.1a}$$

$$R_{\rm Cullis} = \sum_{hkl} \big|F_{\rm PH} - |F_{\rm P} + F_{\rm H}|\big| \Big/ \sum_{hkl} |F_{\rm PH} - F_{\rm P}|. \tag{2.2.5.1b}$$

Anomalous Cullis *R* factor, $R_{\rm Cullis,ano}$. The Cullis R factor for phase determination by anomalous dispersion is defined as the ratio between the lack-of-closure error and the observed anomalous difference $|F_{\rm PH}(hkl) - F_{\rm PH}(\bar{h}\bar{k}\bar{l})|$. The lack-of-closure error in the anomalous-dispersion case is the difference between the observed anomalous difference and the calculated anomalous difference $2F_{\rm H}\sin\alpha_{\rm P}$, where $\alpha_{\rm P}$ is the protein phase. A value of $R_{\rm Cullis,ano} < 1.0$ suggests that a contribution to the phasing from the anomalous data is likely (*MLPHARE* program documentation; Collaborative Computational Project, No. 4, 1994).

$$R_{\rm Cullis,ano} = \frac{\sum_{hkl} \big||F_{\rm PH}(hkl) - F_{\rm PH}(\bar{h}\bar{k}\bar{l})| - |2F_{\rm H}\sin\alpha_{\rm P}|\big|}{\sum_{hkl} |F_{\rm PH}(hkl) - F_{\rm PH}(\bar{h}\bar{k}\bar{l})|}. \tag{2.2.5.2}$$

Phasing power, $\mathbf{PP}_{\rm iso}$. The isomorphous phasing power $\mathrm{PP}_{\rm iso}$ for phase determination by isomorphous replacement is defined for a particular pair of native and heavy-atom-derivative data sets as the ratio of $|F_{\rm H}|$ and $\varepsilon(\varphi_{\rm P})$, where $|F_{\rm H}|$ is the calculated amplitude of the heavy-atom structure factor and $\varepsilon(\varphi_{\rm P})$ is the lack-of-closure error [equation (2.2.5.1*a*)]. $\mathbf{F}_{\rm P} + \mathbf{F}_{\rm H}$ is a vector sum of the calculated structure factor $\mathbf{F}_{\rm H}$ and the structure factor $\mathbf{F}_{\rm P}$.

$$\mathrm{PP}_{\rm iso} = \sum_{hkl} |F_{\rm H}| \Big/ \sum_{hkl} \big|F_{\rm PH} - |F_{\rm P} + F_{\rm H}|\big|. \tag{2.2.5.3}$$

There is another, slightly different, definition of $\mathrm{PP}_{\rm iso}$, which is implemented in the program *SOLVE*. Here, $\mathrm{PP}_{\rm iso}$ is defined as the ratio of the r.m.s. of the $|F_{\rm H}|$ values and the r.m.s. of the lack-of-closure errors $\varepsilon(\varphi_{\rm P})$. For each reflection hkl, a weighted average of $\varepsilon(\varphi_{\rm P})$ is calculated by integrating $\varepsilon(\varphi_{\rm P})$ over the whole phase circle.

$$\mathrm{PP}_{\rm iso} = \Big(\sum_{hkl} |F_{\rm H}|^2\Big)^{1/2} \Big/ \Big(\sum_{hkl} \langle\big|F_{\rm PH} - |F_{\rm P} + F_{\rm H}|\big|\rangle^2\Big)^{1/2}. \tag{2.2.5.4}$$

Note. Owing to the cancelling out of the factor $N^{1/2}$ in the numerator and denominator, the latter $\mathrm{PP}_{\rm iso}$ formula does not appear as a ratio of r.m.s. values at first sight.

Anomalous phasing power, $\mathbf{PP}_{\rm ano}$. The anomalous phasing power $\mathrm{PP}_{\rm ano}$ for phase determination by anomalous-dispersion methods is defined as the ratio of the sum of calculated anomalous differences $d''_{\rm calc}$ and the sum of estimated standard uncertainties $\sigma(d''_{\rm obs})$ in the measurement of these anomalous differences:

$$\mathrm{PP}_{\rm ano} = \sum_{hkl} d''_{\rm calc} \Big/ \sum_{hkl} \sigma(d''_{\rm obs}). \tag{2.2.5.5}$$

As with $\mathrm{PP}_{\rm iso}$ (see above), the program *SOLVE* uses a slightly different definition of $\mathrm{PP}_{\rm ano}$. Here, the anomalous phasing power is defined as the ratio of the r.m.s. of the $d''_{\rm calc}$ values and the r.m.s. of $\sigma(d''_{\rm obs})$. For this, a weighted average of $d''_{\rm calc}$ is computed by integrating over the whole phase circle for each reflection.

$$\mathrm{PP}_{\rm ano} = \Big(\sum_{hkl} \langle d''_{\rm calc}\rangle^2\Big)^{1/2} \Big/ \Big[\sum_{hkl} \sigma(d''_{\rm obs})^2\Big]^{1/2}. \tag{2.2.5.6}$$

Note. As above in the $\mathrm{PP}_{\rm iso}$ formula, the factors $N^{1/2}$ in the numerator and denominator cancel out.

Figure of merit (f.o.m.), *m*. The figure of merit m is a term used in a number of contexts in X-ray crystallography. In its most common use, it is defined as the weight applied to an individual structure-factor amplitude that, in conjunction with its best phase, gives rise, in a Fourier synthesis, to the electron-density map with the minimum level of noise (Blow & Crick, 1959). Typically, m is given as an average value over all reflections in the data set or in a given resolution shell.

$$m = \int P(\alpha)\exp(i\alpha)\,{\rm d}\alpha \Big/ \int P(\alpha)\,{\rm d}\alpha = \langle\cos(\Delta\alpha)\rangle, \tag{2.2.5.7}$$

where $P(\alpha)$ is the probability of the phase α, initial or refined, being the best phase and $\Delta\alpha = \alpha_{\rm best} - \alpha$ is the error in the phase angle at α. The integration is from 0 to 2π and values for m range from 0 to 1.

2.2.6. Quality indicators for density modification and phase improvement

After determination of initial phases, a first electron-density map can be computed. It is expected that this map will contain significant errors and improbable features. Additional information, such as the flatness of the electron density in the solvent region or the similarity of electron-density regions of two or more identical molecules in the asymmetric unit, can be exploited to modify the electron density and hence improve the phases.

Figure of merit (f.o.m.), *m*. The figure of merit m [see equation (2.2.5.7)] is also used to judge the degree of improvement in the phase values. Again, in its most common use, it is defined as the weight applied to an individual structure-factor amplitude that, in conjunction with its best phase, gives rise, in a Fourier synthesis, to the electron-density map with the minimum level of noise. Typically, m is given as an average value over all reflections in the data set or in a given resolution shell.

Density-modification (DM) free *R* factor. The DM free R factor is defined in the same way as the refinement free R factor $R_{\rm free}$ [see equation (2.2.8.1) and the following paragraph describing $R_{\rm free}$]. It describes the disagreement between the observed structure-factor amplitudes of a certain set of reflections and the calculated amplitudes after density modification. It is a weak indicator used in the program *DM* (Cowtan, 1999) and is helpful mainly in identifying the correct enantiomorph.

Density-modification (DM) real-space free residuals. The DM real-space free residuals are two numbers (real-space free residual for the solvent area and real-space free residual for the protein area) which are calculated by omitting two small spheres of protein and solvent from the density-modification process. The real-space free residual for the solvent area indicates how flat the solvent is in a non-flattened region of solvent and the real-space free residual for the protein area indicates how well the electron density in a non-histogram-matched region of protein obeys the expected histogram. The two residuals can also be combined into the combined real-space free residual by weighted summation, where the weight is defined by the solvent content. The DM real-space free residuals have some value in determining when to stop a density-modification calculation, once no more progress is being made, but limited value otherwise.

Contrast, *c*. The contrast c between the r.m.s. electron density in the solvent region and the r.m.s. electron density in the macromolecular region can serve as an indication of the presence of a clearly-defined solvent boundary in the electron-density map. It is defined as the standard deviation of the local r.m.s. electron-density values over the entire asymmetric unit (Terwilliger & Berendzen, 1999; Sheldrick, 2002; Terwilliger *et al.*, 2009). The electron-density values are first squared (optionally after truncating very high and very low density values) and then smoothed using a moving local sphere typically with a radius of 6 Å. Local r.m.s. values are then calculated. The contrast c is now defined as the standard deviation σ of the local r.m.s. density values multiplied by a factor to normalize for the fraction of solvent sc in the crystal:

$$c = [(1 - sc)/sc]^{1/2}\sigma. \qquad (2.2.6.1)$$

Skewness of electron density, *S*. A high value for the skewness S of the electron density in an electron-density map indicates the presence of local electron-density maxima with high positive density values. The skewness is defined as the third moment of the electron density:

$$S = \langle\rho^3\rangle/\langle\rho^2\rangle^{3/2}. \qquad (2.2.6.2)$$

In order to compute the mean values of ρ^3 and ρ^2, all density grid points in the asymmetric unit of the electron-density map are taken into account (Terwilliger *et al.*, 2009).

Overlap of NCS-related density, $O_{\rm NCS}$. The presence of correlated electron density at noncrystallographic symmetry (NCS)-related regions in a map can be used as an indicator for the quality of the electron-density map (Cowtan & Main, 1998; Vellieux *et al.*, 1995; Terwilliger *et al.*, 2009). The overlap ($O_{\rm NCS}$) between density values at NCS-related locations is also often used to evaluate the presence of local symmetry or non-space-group symmetry:

$$O_{\rm NCS} = \langle\rho_i\rho_j\rangle. \qquad (2.2.6.3)$$

ρ_i and ρ_j are the normalized electron-density values in the NCS-related regions in the asymmetric unit. The average is calculated over the whole region where NCS is present. This region may be defined as the region where overlap values are 0.3 or greater, or by a mask. If there are more than two NCS groups, the average is taken over all NCS pairs.

***R* factor, $R_{\rm DENMOD}$, and phase correlation, $m_{\rm DENMOD}$, from statistical density modification.** The amplitudes and phases of structure factors calculated using statistical density modification can be compared with the observed amplitudes and experimental phases (Cowtan & Main, 1996; Terwilliger, 2001; Terwilliger *et al.*, 2009). These comparisons yield an R value ($R_{\rm DENMOD}$) for the amplitudes and a mean cosine of the phase difference ($m_{\rm DENMOD}$) for the phases.

$$R_{\rm DENMOD} = \sum_{hkl} \big||F_{\rm obs}| - |F_{\rm DENMOD}|\big| / \sum_{hkl} |F_{\rm obs}|, \qquad (2.2.6.4)$$

$$m_{\rm DENMOD} = (1/N) \sum_{hkl} \cos(\alpha_{\rm obs} - \alpha_{\rm DENMOD}). \qquad (2.2.6.5)$$

Correlation coefficient CC of chain trace against native data. The quality of density modification in *SHELXE* (Sheldrick, 2002, 2010) can be assessed by computing a Pearson linear correlation coefficient [see equation (2.2.2.13)] of the calculated structure-factor amplitudes for a chain trace against the native structure-factor amplitudes. If the poly-Ala trace yields a CC value higher than 0.25 and if the mean chain length of the trace is >10, the solution is almost always correct. This criterion is currently implemented in the program *ARCIMBOLDO* (Rodriguez *et al.*, 2009).

2.2.7. Quality indicators for molecular replacement

In a case where a known structure is assumed to be similar to that of a target molecule (structural similarity is typically inferred by the degree of sequence similarity), the known structure, also termed the search model, can be used to determine the structure of the target molecule. The approach, termed molecular replacement, was first described in 1962 (Rossmann & Blow, 1962). Nowadays, about two thirds of all newly determined structures are determined by molecular replacement (Long *et al.*, 2008).

Rotation function, RF. The rotation function RF is a measure of the overlap or the agreement of the stationary Patterson function $P2$ calculated from the observed data and the rotated Patterson function $P1$ from the search model.

$$\mathrm{RF} = \int_r P2\, \underline{R}\, P1 \,\mathrm{d}r. \qquad (2.2.7.1)$$

In the equation for RF, $\underline{\mathrm{R}}$ is the rotation operator. The integration is performed between a minimum value and a maximum value for the radius r. These values are chosen according to the size of the search model, with the aim of including as many intramolecular Patterson peaks (self vectors) as possible and to exclude as many intermolecular Patterson peaks (cross vectors) as possible. The ratio of the height of a peak in the RF to the background level is used as an indicator of how likely it is that this peak describes the orientation of a molecule in the target structure.

Translation function, TF. There are numerous ways of defining a translation function TF, making it impractical to discuss quality indicators here. For a thorough treatment of translation-function applications, the reader is referred to Chapter 2.3 of *International Tables for Crystallography* Volume B and Chapter 13.3 of the present volume.

Log-likelihood gain, LLG. In likelihood-based molecular replacement (McCoy *et al.*, 2007), potential molecular-replacement solutions are evaluated using likelihood, which is defined as the probability P that the observed diffraction data would have been measured if the orientation (and, usually, position) of the model were correct (Read, 2001). The score is reported in terms of the log-likelihood gain (LLG), which is defined as the logarithm of the likelihood score for the model $p(F_{\rm obs}; \text{model})$ minus the logarithm of the likelihood score for a random-atom Wilson distribution $p_{\rm Wilson}(F_{\rm obs})$. The LLG measures how much better the data can be predicted from the molecular-replacement model than from a collection of random atoms.

$$\mathrm{LLG} = \sum_{hkl} \ln[p(F_{\rm obs}; \text{model})] - \sum_{hkl} \ln[p_{\rm Wilson}(F_{\rm obs})]. \qquad (2.2.7.2)$$

LLG-Z score. It is important to note that the LLG depends on the quality of the model and the number of reflections, so the absolute values cannot be compared between different molecular-replacement applications. Instead, the quality of a molecular-replacement solution can be judged by the LLG-Z score, which is defined as the number of standard deviations a score is above the mean score in a particular rotation or translation search.

$$\text{LLG-Z} = \mathrm{LLG} - \langle \mathrm{LLG} \rangle / [(\mathrm{LLG} - \langle \mathrm{LLG} \rangle)^2]^{1/2}. \qquad (2.2.7.3)$$

The translation function Z score (TFZ) for the last component placed in a molecular-replacement search is often a good indicator of the confidence that can be placed in the solution. If TFZ is greater than 8 and there is no translational pseudo-symmetry, the solution is almost always correct.

Detailed descriptions of the background and proper application of molecular-replacement approaches are presented in Chapter 2.3 of *International Tables for Crystallography* Volume B and Chapters 13.2 and 13.3 of the present volume.

2.2.8. Quality indicators for refinement

The last step of a structure determination is the refinement of the model against the observed data. Refinement is in principle a mathematical operation that is applied in order to minimize the discrepancy between the observed structure-factor amplitudes $|F_{\rm obs}|$ and the calculated ones $|F_{\rm calc}|$.

Crystallographic *R* factor, *R*. The crystallographic R factor R is defined as the fractional disagreement between the set of observed structure-factor amplitudes and amplitudes calculated from the structural model. Of course, observed and calculated reflection sets need to be on the same scale.

$$R = \sum_{hkl} \big||F_{\rm obs}| - |F_{\rm calc}|\big| / \sum_{hkl} |F_{\rm obs}|. \qquad (2.2.8.1)$$

Free *R* factor, $R_{\rm free}$. The free R factor $R_{\rm free}$ is defined in the same way as the crystallographic R factor, but it is based on a set of reflections that have been excluded from the refinement (Brünger, 1992). The excluded set of reflections is called the *test set*, while the set of reflections used for refinement is called the *working set*. The test set can be chosen randomly or systematically, either in thin resolution shells or to account for the presence of noncrystallographic symmetry, respectively. In order to minimize the impact on the final model, the test set should be as small as possible. Typically, it contains about 5–10% of the reflections, or at least enough reflections to keep the standard deviation of $R_{\rm free}$ below 1%, but there is no need to use more than 2000 reflections (Kleywegt & Brünger, 1996; Brünger, 1997). The standard deviation of $R_{\rm free}$ has been empirically estimated to be $R_{\rm free}/N^{1/2}$, where N is the number of reflections in the test set (Brünger, 1997). Of course, there may be concerns about the impact of excluding 5–10% of reflections on the final model, but a few final cycles of refinement against the recombined full data set should allay them.

Correlation coefficients CC($F_{\rm obs}$, $F_{\rm calc}$) and CC($I_{\rm obs}$, $I_{\rm calc}$). CC($F_{\rm obs}$, $F_{\rm calc}$) and CC($I_{\rm obs}$, $I_{\rm calc}$) are Pearson linear correlation coefficients [see equation (2.2.2.13)] between observed and model-based calculated structure-factor amplitudes or intensities, respectively, that find use from time to time. One advantage of the use of a correlation coefficient instead of an R factor is that it avoids the problem of scaling the two sets of numbers relative to each other.

2.2.9. Quality indicators for the refined model

In MX, the observable-to-parameter ratio is mostly unfavourable. Therefore, structure refinements are carried out with boundary conditions, constraints and restraints. Constraints reduce the number of parameters which need to be refined, while restraints provide additional information to the refinement procedure that increases the number of observables. A refined model, therefore, has to fulfil not only the criterion that the crystallographic R factor [see equation (2.2.8.1)] is good and that the model fits well to the electron density, but also that it fits well to the restraints used in the refinement procedure.

Real-space residual, RSR. The real-space residual, RSR (Jones *et al.*, 1991), quantifies the discrepancies between the electron-density maps ρ_1, calculated directly from a structural model, and ρ_2, calculated from experimental data. RSR can take the form of a real-space R factor RSRF and of a real-space correlation coefficient RSCC.

$$\mathrm{RSRF} = 2 \sum_{xyz} |\rho_1 - \rho_2| / \sum_{xyz} (\rho_1 + \rho_2). \qquad (2.2.9.1)$$

The sum $\sum_{xyz}$ runs over all grid points of the electron-density maps that are close to the model. A big advantage of RSRF is that is can be calculated on a residue-by-residue basis. It therefore gives a local picture of structure quality. It can also be used throughout model building and refinement in order to follow the improvement of the model locally on a per-residue basis.

RSCC is defined as the Pearson linear correlation coefficient [see equation (2.2.2.13)] between ρ_1 and ρ_2. Everything said about RSRF above applies to RSCC as well.

R.m.s. deviation from ideal of geometric parameter *x*. The root-mean-square deviation of a set of geometric parameters x from their ideal values is defined as

$$\mathrm{r.m.s.d.}(x) = \Big\{ \sum_i [x_i(\text{ideal}) - x_i(\text{observed})]^2 / N \Big\}^{1/2}. \qquad (2.2.9.2)$$

The sum runs over all N instances of the geometric parameter occurring in a structure. The geometric parameters x that are typically considered are bond lengths, bond angles, dihedral angles, chiral volumes, planar groups *etc*. The ideal values for proteins are typically taken from the study of Engh & Huber (1991) and for nucleic acids from Parkinson *et al.* (1996).

***Z* score**. A measure of the likelihood that an individual geometric parameter is correct is given by its Z score. The Z score is defined as the distance of an individual data point of a distribution from the mean of the distribution expressed in standard

Table 2.2.11.1
Definitions of the most commonly used quality indicators

Indicator	Details
Optical resolution, $d_{\rm opt} = [2(\sigma^2_{\rm Patt} + \sigma^2_{\rm sph})]^{1/2}$ (2.2.2.2)	$\sigma_{\rm Patt}$ and $\sigma_{\rm sph}$ are the standard uncertainties of Gaussians fitted to the origin peak of the Patterson function of the diffraction data set and the origin peak of the spherical interference function, respectively
$R_{\rm merge}$ (merging *R* factor), $R_{\rm merge} = \sum_{hkl}\sum_{i} \vert I_i(hkl) - \langle I(hkl)\rangle\vert / \sum_{hkl}\sum_{i} I_i(hkl)$ (2.2.2.4)	$\langle I(hkl)\rangle$ is the mean of the several individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*
$R_{\rm meas}$ or $R_{\rm r.i.m}$ (redundancy-independent merging *R* factor), $R_{\rm r.i.m.} = \sum_{hkl}\{N(hkl)/[N(hkl)-1]\}^{1/2}\sum_{i} \vert I_i(hkl) - \langle I(hkl)\rangle\vert / \sum_{hkl}\sum_{i} I_i(hkl)$ (2.2.2.5)	$\langle I(hkl)\rangle$ is the mean of the $N(hkl)$ individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*
$R_{\rm p.i.m.}$ (precision-indicating merging *R* factor), $R_{\rm p.i.m.} = \sum_{hkl}\{1/[N(hkl)-1]\}^{1/2}\sum_{i} \vert I_i(hkl) - \langle I(hkl)\rangle\vert / \sum_{hkl}\sum_{i} I_i(hkl)$ (2.2.2.6)	$\langle I(hkl)\rangle$ is the mean of the $N(hkl)$ individual measurements $I_i(hkl)$ of the intensity of reflection *hkl*
$R_{\rm anom}$ (anomalous *R* factor), $R_{\rm anom} = \sum_{hkl} \vert I(hkl) - I(\bar{h}\bar{k}\bar{l})\vert / \sum_{hkl}\langle I(hkl)\rangle$ (2.2.2.12)	$\langle I(hkl)\rangle$ is the mean intensity of the Friedel mates of the reflection *hkl*, or $\frac{1}{2}[I(hkl) + I(\bar{h}\bar{k}\bar{l})]$
$\rm R_{Cullis}$ (Cullis *R* factor for isomorphous-replacement applications), $R_{\rm Cullis} = \sum_{hkl} \big\vert F_{\rm PH} - \vert F_{\rm P} + F_{\rm H}\vert \big\vert / \sum_{hkl} \vert F_{\rm PH} - F_{\rm P}\vert$ (2.2.5.1*b*)	$F_{\rm P}$, $F_{\rm PH}$ and $F_{\rm H}$ are the structure factors for the protein, the heavy-atom derivative and the heavy atoms alone, respectively
$\rm PP_{iso}$ (phasing power for isomorphous-replacement applications), $\mathrm{PP_{iso}} = \sum_{hkl} \vert F_{\rm H}\vert / \sum_{hkl} \big\vert F_{\rm PH} - \vert F_{\rm P} + F_{\rm H}\vert \big\vert$ (2.2.5.3) or, as in the program *SOLVE*, $\mathrm{PP_{iso}} = (\sum_{hkl} \vert F_{\rm H}\vert^2)^{1/2} / (\sum_{hkl} \langle \big\vert F_{\rm PH} - \vert F_{\rm P} + F_{\rm H}\vert \big\vert \rangle^2)^{1/2}$ (2.2.5.4)	$F_{\rm P}$, $F_{\rm PH}$ and $F_{\rm H}$ are the structure factors for the protein, the heavy-atom derivative and the heavy atoms alone, respectively
R (crystallographic *R* factor) and $R_{\rm free}$ (free *R* factor), $R = \sum_{hkl} \big\vert \vert F_{\rm obs}\vert - \vert F_{\rm calc}\vert \big\vert / \sum_{hkl} \vert F_{\rm obs}\vert$ (2.2.8.1)	$R_{\rm free}$ is defined as the crystallographic *R* factor but for a subset of reflections that have been excluded from refinement
RSRF (real-space *R* factor), $\mathrm{RSRF} = 2\sum_{xyz} \vert \rho_1 - \rho_2\vert / \sum_{xyz}(\rho_1 + \rho_2)$ (2.2.9.1)	ρ_1 and ρ_2 are the electron-density maps calculated from the structural model and from the experimental data, respectively
R.m.s.d.'s of geometric parameters *x*, $\mathrm{r.m.s.d}(x) = \{\sum_{i}[x_i(\mathrm{ideal}) - x_i(\mathrm{observed})]^2/N\}^{1/2}$ (2.2.9.2)	x_i are the individual values, ideal or observed, of the geometric parameter *x* and the sum is over all *N* x_i observed. The geometric parameters *x* may be bond lengths, bond angles, dihedral angles, chiral volumes, deviations from planarity *etc*.
DPI (diffraction-component precision index), $\mathrm{DPI} = [N_{\rm atom}/(N_{hkl} - N_{\rm para})]^{1/2} R d_{\rm min} C^{-1/3}$ (2.2.10.1)	$N_{\rm atom}$ is the number of atoms in the structure, N_{hkl} is the number of reflections, $N_{\rm para}$ is the number of refined parameters, *R* is the crystallographic *R* factor, $d_{\rm min}$ is the nominal resolution and *C* is the fractional completeness of the data set

deviations. In the case described here, the mean values of the distribution are the ideal values taken from Engh & Huber (1991) and Parkinson *et al.* (1996).

$$Z(x_i) = [x_i(\text{observed}) - x_i(\text{ideal})]/\sigma(x). \qquad (2.2.9.3)$$

Ideally, the Z score should be 0. A parameter that exhibits a Z score of less than -4 or greater than $+4$ is highly unlikely and calls for attention.

Root-mean-square Z score, r.m.s.-Z. Although r.m.s.d. values [see equation (2.2.9.2)] are still popular for use in judging the quality of refined macromolecular models, a much more useful statistic is the r.m.s. value of a distribution of Z scores or the r.m.s.-Z score.

$$\text{r.m.s.-Z}(x) = \sum_i [Z(x_i)^2/N]^{1/2}. \qquad (2.2.9.4)$$

The sum runs over all N instances of the geometric parameter x occurring in a structure. A very useful property of Z scores is that the r.m.s. values of Z-score distributions should always be 1. Significant deviations from the ideal value indicate potential problems. R.m.s. Z scores are widely used, for instance, in the program *WHAT_CHECK* (Hooft *et al.*, 1996).

R.m.s.d. (NCS). The root-mean-square deviation from crystallographic symmetry between two molecules related by non-crystallographic symmetry (NCS) can be calculated from a superposition of the two molecules. It is defined as

$$\text{r.m.s.d.(NCS)} = \left(\sum_i d_i^2/N\right)^{1/2}. \qquad (2.2.9.5)$$

The sum runs over N equivalent atom pairs with d_i being the distance between the two equivalent atoms after superposition.

2.2.10. Error estimation for the refined model

An important quality indicator for a refined model is the coordinate uncertainty. Short of full-matrix inversion, which is the standard procedure in small-molecule crystallography but which is applicable only in exceptional cases for macromolecules, some methods have been devised for estimating of the overall coordinate uncertainty.

Error estimation according to Luzzati. For most macromolecular structure determinations, atomic standard uncertainties are not available. However, Luzzati (1952) devised a method of estimating the average positional error of a structure. Under the assumption that the atomic positional errors follow a normal distribution, the average error can be estimated by comparing a plot of the crystallographic R factor [see equation (2.2.8.1)] *versus* the reciprocal resolution (or 2 sin θ/λ) with pre-computed theoretical curves for different average errors. A more recent – and probably better – approach is to use the free R factor instead of the crystallographic R factor.

SigmaA- (σ_A)-type error estimation. A slightly better estimate of the average positional error of a structure can be obtained by plotting the natural logarithm of the parameter σ_A *versus* $(\sin\theta/\lambda)^2$ (Read, 1986). The slope of a straight line fitted to the plot provides an estimate of the average positional error of the structure. The parameter σ_A assumes normally distributed positional errors and takes model incompleteness into account as well.

Diffraction-component precision index, DPI. The diffraction-component precision index DPI is an empirical parameter describing the overall coordinate uncertainty of a structure (Cruickshank, 1999*a*,*b*). For an atom with an isotropic displacement parameter of average value (B_{avg}), it is defined as

$$\text{DPI} = [N_{\text{atom}}/(N_{hkl} - N_{\text{para}})]^{1/2} R d_{\min} C^{-1/3}, \qquad (2.2.10.1)$$

where N_{atom} is the number of atoms included in the refinement, N_{hkl} is the number of reflections included in the refinement, N_{para} is the number of refined parameters, R is the crystallographic R factor, $d_{\min}$ is the nominal resolution of the data included in the refinement and C is the data completeness. The free R factor R_{free} is sometimes used instead of the crystallographic R factor R to calculate the DPI. In this case $(N_{hkl} - N_{\text{para}})$ is replaced by N_{free}, which is the number of reflections used for R_{free} calculation.

The Cruickshank formula for DPI has been recast into several other forms, including

$$\text{DPI} = \sigma(x, B_{\text{avg}}) = 0.18(1 + sc)^{1/2} V_M^{-1/2} R_{\text{free}} d_{\min}^{5/2} C^{-5/6} \qquad (2.2.10.2)$$

(Blow, 2002), where sc is the solvent fraction ($= N_{\text{solv}}/N_{\text{atom}}$, where N_{solv} is the number of atoms that are solvent) and V_M is the Matthews parameter (Matthews, 1968). The utility of this latter formula in guiding the design of the data-collection experiment to achieve a specified target coordinate uncertainty has been demonstrated (Fisher *et al.*, 2008).

2.2.11. The most commonly used quality indicators

A summary of the most commonly used quality indicators and their definitions is presented in Table 2.2.11.1 for ready reference.

PART 3. TECHNIQUES OF MOLECULAR BIOLOGY

Chapter 3.1. Preparing recombinant proteins for X-ray crystallography

S. H. Hughes and A. M. Stock

3.1.1. Introduction

Preparing protein crystals appropriate for X-ray diffraction usually requires a considerable amount of highly purified protein. When crystallographic methods were first developed, the practitioners of the art were compelled to study proteins that could be easily obtained in large quantities in relatively pure form; the first proteins whose structures were solved by crystallographic methods were myoglobin and haemoglobin. Unfortunately, some of the most interesting proteins are normally present in relatively small amounts, which, while it did not prevent crystallographers from dreaming about their structures, prevented any serious attempts at crystallization. Recombinant DNA techniques changed the rules: it is now possible to instruct a variety of cells and organisms to make large amounts of almost any protein chosen by the investigator. Not only can specific proteins be expressed in large quantities, recombinant proteins can be modified in ways that make the task of the crystallographer simpler and can, in some cases, dramatically improve the quality of the resulting crystals. It is not our intention in writing this chapter to provide either a methods manual for those interested in expressing a particular protein or a complete compendium of the available literature. The literature is vast and complex, and, as we will discuss, the problems associated with expressing a particular protein are often idiosyncratic, making it difficult to provide a simple, comprehensive, methodological guide. What we intend is to discuss issues (and problems) relevant to choosing methods appropriate for preparing recombinant proteins for X-ray crystallography. In this way, we hope to help readers understand both the extant problems and the available solutions, so that, armed with a general understanding of the issues, they can more easily confront a variety of specific projects.

Fortunately, there are a large number of additional resources available to those who are interested in expressing and purifying recombinant proteins, but lack the expertise. These include numerous methods books (*e.g.* on molecular biology: Sambrook *et al.*, 1989; Ausubel *et al.*, 1995; on protein purification: Abelson & Simon, 1990; Scopes, 1994; Bollag *et al.*, 1996), useful reviews of the literature (cited throughout), formal courses (such as those offered by Cold Spring Harbor Laboratory), meetings (*i.e.* IBC's International Conference on Expression Technologies, Washington DC, 1997) and a specialized journal (*Protein Expression and Purification*). The pace of methodological development is rapid, and company catalogues, publications and web pages can provide extensive, useful, up-to-date information. In many cases, a convenient source of information is a nearby researcher whose own research depends on expressing and purifying recombinant proteins. Those who are serious about preparing recombinant proteins for crystallography, but have little or no experience, are strongly urged to avail themselves of these resources. In many cases the help of a knowledgeable colleague is the most valuable resource. In general, the literature provides a much better guide to what will work than what will fail; quite often, in designing a good strategy to produce a recombinant protein that is suitable for crystallography, it is more important to understand the potential pitfalls. Discussion with an experienced colleague is usually the best way to avoid the most obvious errors.

Section 3.1.2 gives an overview of the problem, Section 3.1.3 discusses engineering an expression construct, Section 3.1.4 discusses expression systems, Section 3.1.5 discusses protein purification and Section 3.1.6 discusses the characterization of the purified product.

3.1.2. Overview

The idea that underlies the problem of expressing large amounts of a recombinant protein is straightforward: prepare a DNA segment that, when introduced into an appropriate host, will cause the abundant expression of the relevant protein. However, as the saying goes, 'The devil is in the details.' Not only is it necessary to design the appropriate DNA segment, but also to introduce it into an appropriate host such that the host retains and faithfully replicates the DNA. The DNA segment must contain all of the elements necessary for high-level RNA expression; moreover, the RNA, when expressed, must be recognized by the translational machinery of the host. The recombinant protein, once expressed, needs to be properly folded either by the host or, if not properly folded in the host, by the experimentalist. If the protein is subject to post-translational modifications (cleavage, glycosylation, phosphorylation *etc.*) and the experimentalist wishes to retain these modifications, the appropriate signals must be present and the chosen host must also be capable of recognizing the signals. Once the recombinant protein is expressed, assuming it is reasonably stable in the chosen host, the protein must be purified; as we will discuss, recombinant proteins can be modified to simplify purification. Once purified, the quality of the protein preparation must be evaluated to ensure it is both relatively homogeneous and monodisperse.

While this chapter will be limited to discussions of the basic strategies for creating an expression vector, expressing the protein and purifying and characterizing the product, molecular biological methods can be used in other ways that are relevant to crystallography. In some cases, a protein in its natural form is not suitable for crystallization. Crystallographers have long used proteolytic digestion and/or glycolytic digestion to produce proteins suitable for crystallization from ones that are not. Such techniques have been used to good effect on recombinant proteins; however, the ability to modify the segment encoding the protein makes it possible to alter the protein in a variety of ways beyond simple enzymatic digestions. Specific examples of such applications are described in Chapter 4.3.

Unfortunately, no single strategy for producing proteins for crystallization appears to be universally successful. Any parti-

cular protocol has the potential for displaying undesirable behaviour at any step during the process of expression, purification or crystallization. It is important to distinguish major and minor problems. If the problems are serious, it is often better to try an alternative strategy than to struggle with an inappropriate system. Because it is usually difficult to predict what will work and what will not, often the most expedient route to successful expression of a protein for crystallization is the simultaneous pursuit of several expression strategies with multiple protein expression constructs.

3.1.3. Engineering an expression construct

3.1.3.1. Choosing an expression system

The first step in developing an expression strategy is the choice of an appropriate expression system, and this decision is critical. As we will discuss briefly below, the rules and/or sequences necessary to express RNA and proteins in *E. coli*, yeast and insect cells (baculoviruses) differ to a greater or lesser extent from those used in higher eukaryotes, and there are considerable differences in the post-translational modifications of proteins in these different systems or organisms. Quite often the protein chosen for investigation comes from a higher eukaryote or from a virus that replicates in higher eukaryotes. The experimentalist prefers to obtain large amounts of the protein (>5–10 mg) to set up crystallization trials. In theory, one simple solution is to use a closely related host to express the protein of interest. While it is possible to produce large amounts of proteins in cultured animal cells (and in some cases in transgenic animals), the difficulties and expense of these approaches usually prevent their use for most projects that require large amounts of highly purified recombinant protein.

In general, prokaryotic (*E. coli*) expression systems are the easiest to use in terms of the preparation of the expression construct, the growth of the recombinant organism and the purification of the resulting protein. Additionally, they allow for relatively easy incorporation of selenomethionine into the recombinant protein (Hendrickson *et al.*, 1990), which is an important consideration for crystallographers intending to use multiple anomalous dispersion (MAD) phasing techniques. However, the differences between *E. coli* and higher eukaryotes means that, in some cases, the recombinant protein must be modified to permit successful expression in *E. coli*, and the available *E. coli* expression systems cannot produce many of the post-translational modifications made in higher eukaryotes. As one moves along the evolutionary path from *E. coli* to yeast, to baculovirus and finally to cultured mammalian cells, the problems associated with producing the protein in its native state are simpler, while the problems associated with expressing large amounts of material quickly, simply and cheaply in an easy-to-purify form become more difficult. In Section 3.1.4, we will consider each of these expression systems in turn; first we will briefly discuss, in a general way, how the relevant genes or cDNA strands are obtained and how an expression system is designed.

3.1.3.2. Creating an expression construct

The first step in preparing an expression system is obtaining the gene of interest. This is not nearly as daunting a task as it once was; an intense effort is now being directed at genome sequencing and the preparation of cDNA clones from a number of prokaryotic and eukaryotic organisms. There are also a large number of cloned viral genes and genomes. This means that, in most cases, an appropriate gene or cDNA can be obtained without the need to prepare a clone *de novo*. If the nucleic sequence is available, but the corresponding cloned DNA is not, it is usually a simple matter to prepare the desired DNA clone using the polymerase chain reaction (PCR). If the relevant genomic or cDNA clone is not available and there is no obvious way to obtain it, there are established techniques for obtaining the desired clone; however, these methods are often tedious and labour intensive. They also constitute a substantial field in their own right and, as such, lie beyond the scope of this chapter (for an overview, see Sambrook *et al.*, 1989).

In higher eukaryotes, most mRNA strands are spliced. With minor exceptions, mRNA strands are not spliced in *E. coli*. In yeast, the splicing rules do not match those used in higher eukaryotes. If one expects to express a protein from a higher eukaryote in one of these systems, a cDNA must be prepared or obtained. Because some introns are large, cDNA clones are often used as the basis of expression constructs in baculovirus systems, as well as in cultured insect and mammalian cells.

In all subsequent discussions, we will assume that the experimentalist possesses both a cDNA that encodes the protein that will be expressed and an accurate sequence. If a genomic clone is available, it can be converted to cDNA form by PCR methods or by using a retroviral vector. Retroviral vectors, by nature of their life cycle, will take a gene through an RNA intermediate, thus removing unwanted introns (Shimotohno & Temin, 1982; Sorge & Hughes, 1982). If a good sequence is not available, one should be prepared. In general, expression constructs are based, more or less exclusively, on the coding region of the cDNA. The flanking 5′ and 3′ untranslated regions are not usually helpful, and if these untranslated regions are included in an expression construct, they can, in some cases, interfere with transcription, translation or both. With some knowledge of the organization of the protein, it is sometimes helpful to express portions of a complex protein for crystallization. This will be discussed in more detail later in this chapter and in Chapter 4.3.

Optimizing the expression of the protein is extremely important. The amount of effort required to get an expression system to produce twice as much protein is usually less than that required to grow twice as much of the host; moreover, the effort to purify a recombinant protein is inversely related to its abundance, relative to the proteins of the host. There are specific rules for expressing a recombinant protein in the different host–vector systems; these will be discussed in the context of using various hosts (*E. coli*, yeast, baculoviruses and cultured insect and mammalian cells).

Although the precise nature of the modifications necessary to obtain efficient expression of a protein is host dependent, the tools used to produce the modified cDNA and link it to an appropriate expression plasmid or other vector are reasonably standard. In recent years, PCR has become the method of choice for manipulation of DNA; it is a relatively easy and rapid method for altering DNA segments in a variety of useful ways (Innis *et al.*, 1990; McPherson *et al.*, 1995). For most construction projects, the ends of the cDNA are modified, using PCR with appropriate oligonucleotide primers that have been designed to introduce useful restriction sites and/or elements essential for efficient transcription and/or translation. Since it can often be advantageous to try the expression of a given protein construct in a number of different vectors, it is useful to incorporate carefully chosen restriction sites that will enable the fragment to be inserted simultaneously, or transferred seamlessly, into different plasmids or other vectors (Fig. 3.1.3.1). PCR can also be used to create mutations in the interior of the cDNA. For some projects

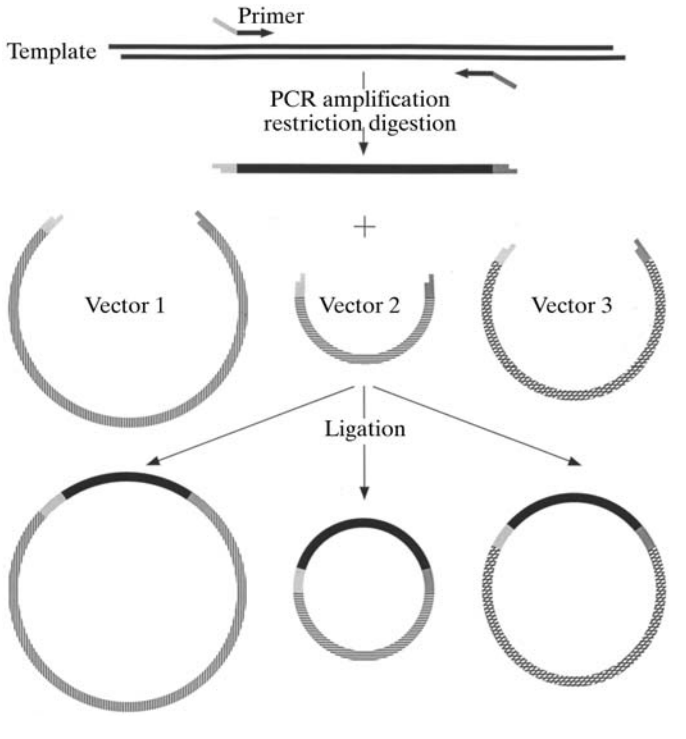

Figure 3.1.3.1
Creating an expression construct. PCR can be used to amplify the coding region of interest, providing that a suitable template is available. PCR primers should be designed to contain one or more restriction sites that can be conveniently used to subclone the fragment into the desired expression vector. It is often possible to choose vectors and primers such that a single PCR product can be ligated to multiple vectors. The ability to test several expression systems simultaneously is advantageous, since it is impossible to predict which vector/host system will give the most successful expression of a specific protein.

where large-scale mutagenesis is planned, other mutagenic techniques are particularly helpful (for example, site-directed cassette mutagenesis using *Bsp* MI or a related enzyme; Boyer & Hughes, 1996). Ordinarily, however, these alternative strategies are only useful if a relatively large number of mutants are needed for the project.

If PCR is used either to modify the ends of a DNA segment or to introduce specific mutations within a segment, it should be remembered that the PCR can introduce unwanted mutations. PCR conditions should be chosen to minimize the risk of introducing unwanted mutations (start with a relatively large amount of template DNA, limit the number of amplification cycles, use relatively stringent conditions for hybridization of the primers, choose solution conditions that reduce the number of errors made in copying the DNA and use enzymes with good fidelity, such as *Pfu* or others that have proofreading capabilities). It is also important to sequence all of the DNA pieces generated by PCR after they have been cloned.

3.1.3.3. Addition of tags or domains

In some cases it is useful to add a small peptide tag or a larger protein to either the amino or carboxyl terminus of the protein of interest (Nilsson *et al.*, 1992; LaVallie & McCoy, 1995). As will be discussed in more detail below, such fused elements can be used for affinity chromatography and can greatly simplify the purification of the recombinant protein. In addition to aiding purification, some protein domains used as tags, such as the maltose-binding protein, thioridazine, and protein A, can also act as molecular chaperones to aid in the proper folding of the recombinant protein (LaVallie *et al.*, 1993; Samuelsson *et al.*, 1994; Wilkinson *et al.*, 1995; Richarme & Caldas, 1997; Sachdev & Chirgwin, 1998). Tags range in size from several amino acids to tens of kilodaltons. Numerous tags [including hexahistidine (His$_6$), biotinylation peptides and streptavidin-binding peptides (Strep-tag), calmodulin-binding peptide (CBP), cellulose-binding domain (CBD), chitin-binding domain (CBD), glutathione S-transferase (GST), maltose-binding protein (MBP), protein A domains, ribonuclease A S-peptide (S-tag) and thioridazine (Trx)] have already been engineered into expression vectors that are commercially available. Additional systems are constantly being introduced. While these systems provide some advantages, there are also drawbacks, including expense, which can be considerable when both affinity purification and specific proteolytic removal of the tag are performed on a large scale.

If a sequence tag or a fusion protein is added to the protein of interest, one problem is solved but another is created, *i.e.* whether or not to try to remove the fused element. During the past year, there have been numerous reports of crystallization of proteins containing His-tags, but there are also unpublished anecdotes about cases where removal of the tag was necessary to obtain crystals. In a small number of cases, additional protein domains present in fusion proteins appear to have aided crystallization (see Chapter 4.3). Experiences with tags appear to be protein specific. There are a number of relevant issues, including the protein, the tag and the length and composition of the linker that joins the two. If the tag is to be removed, it is usually necessary to use a protease. To avoid unwanted cleavage of the desired protein, 'specific' proteases are usually used. When the expression system is designed, the tag or fused protein is separated from the desired protein by the recognition site for the protease. While this procedure sounds simple and straightforward, and has, in some cases, worked exactly as outlined here, there are a number of potential pitfalls. Proteases do not always behave exactly as advertised, and there can be unwanted cleavages in the desired product. Since protease cleavage efficiency can be quite sensitive to structure, it may be more difficult to cleave the fusion joint than might be expected. Unless cleavage is performed with an immobilized protease, additional purification is necessary to separate the protease from the desired protein product. A variation of the classic tag-removal procedure is provided by a system in which a fusion domain is linked to the protein of interest by a protein self-cleaving element called an intein (Chong *et al.*, 1996, 1997).

3.1.4. Expression systems

3.1.4.1. E. coli

If the desired protein does not have extensive post-translational modifications, it is usually appropriate to begin with an *E. coli* host–vector system (for an extensive review of expression in *E. coli*, see Makrides, 1996). Both plasmid-based and viral-based (M13, λ *etc.*) expression systems are available for *E. coli*. Although viral-based vector systems are quite useful for some purposes (expression cloning of cDNA strands, for example), in general, for expression of relatively large amounts of recombinant protein, they are not as convenient as plasmid-based expression systems. Although there are minor differences in the use of viral expression systems and plasmid-based systems, the rules that govern the design of the modified segment are the same and we will discuss only plasmid-based systems. We will first consider general issues related to design of the plasmid, then continue with a discussion of fermentation conditions, and finally address some of the problems commonly encountered and potential solutions.

Basically, a plasmid is a small circular piece of DNA. To be retained by *E. coli*, it must contain signals that allow it to be successfully replicated by the host. Most of the commonly used *E. coli* expression plasmids are present in the cell in multiple copies. Simply stated, in the selection of *E. coli* containing the plasmid, the plasmids carry selectable markers, which usually confer resistance to an antibiotic, typically ampicillin and/or kanamycin. Ampicillin resistance is conferred by the expression of a β-lactamase that is secreted from cells and breaks down the antibiotic. It has been found that, in typical liquid cultures, most of the ampicillin is degraded by the time cells reach turbidity (approximately 10^7 cells ml^{-1}), and cells not harbouring plasmids can overgrow the culture (Studier & Moffatt, 1986). For this reason, kanamycin resistance is being used as the selectable marker in many recently constructed expression plasmids.

There are literally dozens, if not hundreds, of expression plasmids available for *E. coli*, so a comprehensive discussion of the available plasmids is neither practical nor useful. Fortunately, this broad array of choices means that considerable effort has been expended in developing *E. coli* expression systems that are efficient and easy to use (for a concise review, see Unger, 1997). In most cases, it is possible to find expression and/or fermentation conditions that result in the production of a recombinant protein that is at least several per cent of the total *E. coli* protein. This should result in the expression of greater than 5 mg of recombinant protein per litre of culture, making the scale of fermentation reasonable and the job of purification relatively simple.

Broadly speaking, *E. coli* expression systems are either constitutive (that is, they always express the encoded protein) or inducible, in which case a specific change in the culture conditions is necessary to induce the expression of the recombinant protein. As is often the case, both systems have advantages and disadvantages, and both systems have been successfully used to generate recombinant protein for X-ray crystallographic experiments. There is no question that constitutive systems are simple and convenient. However, the high-level expression of even a relatively benign recombinant protein usually puts the *E. coli* host at a selective disadvantage. Unless precautions are taken, the growth and repeated passage of *E. coli* carrying a constitutive expression plasmid tend to select for variants that express lower (and sometimes much lower) levels of the desired recombinant protein than were seen when the clone was first prepared. This can be avoided by storing the stock as plasmid DNA and regularly preparing fresh transformants.

If the desired protein is toxic to *E. coli* (as are a substantial number of recombinant proteins), then an inducible system is required. There are several considerations when choosing an inducible system. The method used to induce the expression of the protein should be compatible with the scale required to produce the recombinant protein. For example, inducible systems which use the bacteriophage λ $p_{\rm L}$ promoter and the temperature-sensitive repressor CI857ts require a temperature shift from approximately 30 to 42 °C. This can be done quite conveniently in small cultures, but it is much more difficult to achieve a rapid shift of temperature if *E. coli* are grown in batches larger than 10 l. Inducible expression systems based on the *lac* repressor are usually induced with isopropyl-β-D-thiogalactopyranoside (IPTG). The cost of this gratuitous inducer is not an issue when *E. coli* are grown in small cultures; however, in large-scale fermentations, the costs of the inducer are nontrivial. Despite this caveat, expression systems controlled by the *lac* repressor are commonly used. In the original *lac*-based inducible expression systems, the *lac* operator/promoter was located on the plasmid, proximal to the 5′ end of the insert. Because expression plasmids are present in multiple copies in *E. coli*, the *lac* repressor must be overexpressed to a substantial degree for it to be present in sufficient quantity to control a plasmid-borne operon. Even if a highly expressed *lac* repressor gene (*lacI*$^{\rm q}$, which produces approximately ten times as much repressor than does the wild type) is expressed from a single chromosomal copy (*i.e.*, provided by the host strain rather than by the vector), repression is rarely complete, and some constitutive expression is generally observed, with only moderately increased levels of expression achieved upon induction. Note that the same plasmid constructs will often give different levels of expression of the plasmid-borne gene in different host strains because of the nature of the *lac* repressor gene (wild-type or *lacI*$^{\rm q}$).

Better control of induction can usually be obtained using a T7 polymerase expression system in a specifically designed vector–host strain pair (Tabor & Richardson, 1985; Studier & Moffatt, 1986; Studier *et al.*, 1990). In such systems, a *lac*-controlled operon that encodes the bacteriophage T7 RNA polymerase is embedded in the genome of the *E. coli* host and is, as a consequence, present in the cell in only one copy. Induction with IPTG leads to the synthesis of the T7 RNA polymerase, which recognizes a promoter sequence that is different from the sequence recognized by *E. coli* RNA polymerase. If the *E. coli* host that carries the T7 RNA polymerase under the control of *lac* also carries a multicopy plasmid, in which the gene of interest is linked to a T7 promoter, the T7 RNA polymerase efficiently produces mRNA from the plasmid; this usually leads to the production of a large amount of the desired recombinant protein. *E. coli* strains that carry a *lac*-inducible T7 RNA polymerase are readily available, as are the corresponding expression plasmids that carry T7 promoters. Some such *E. coli* strains have been specifically engineered so that the expression of the T7 RNA polymerase (and, by extension, the expression of the gene of interest on the plasmid) is tightly regulated (Studier *et al.*, 1990); these strains are particularly useful for expressing recombinant proteins that are toxic to the *E. coli* host. A recent variation on this system uses an *E. coli* strain in which the T7 RNA polymerase gene is under control of the NaCl-induced *proU* promoter (Bhandari & Gowrishankar, 1997). The same plasmids used for other T7 systems can be used with this *E. coli* strain. The osmo-regulated system has the advantages of requiring a much less expensive inducer and, in at least some cases where inclusion-body formation is a problem, of producing higher levels of soluble protein.

Adaptations of a cDNA may be necessary for high-level expression in *E. coli* (Table 3.1.4.1). Although the genetic code is universal, the signals necessary for transcription of RNA and translation of proteins are not. Most *E. coli* expression plasmids contain the recognition/regulation sites necessary for controlling RNA transcription; the signals necessary to initiate translation are not always included in expression plasmids. In *E. coli*, the initiation of translation requires not only an appropriate initiation codon (usually AUG, occasionally GUG), but also a special element, the Shine–Dalgarno sequence, just 5′ of the initiator AUG (Gold *et al.*, 1981; Ringquist *et al.*, 1992). In *E. coli*, the first step in translation involves the binding of the 30S ribosomal subunit and the initiator fMet-tRNA to the mRNA. The Shine–Dalgarno sequence is complementary to the 3′ end of the 16S

Table 3.1.4.1
Strategies for improving expression in *E. coli*

See text for details.

Factor limiting expression	Possible solution
Transcription and/or translation initiation sites	Use vectors with optimized promoter regions
Toxicity	Use inducible expression systems Use mutagenesis to eliminate enzymatic activity Express a domain of the protein
Rare codons	Use plasmids that co-express corresponding tRNA strands Use mutagenesis to optimize codons
Proteolysis	Use protease-deficient host strains Use N-end rules to avoid degradation
Inclusion-body formation	Express the protein as a fusion Co-express chaperone proteins Grow cells at lower temperatures

RNA found in the 30S subunit. Eukaryotic mRNAs do not contain Shine–Dalgarno sequences. Some *E. coli* expression plasmids carry a Shine–Dalgarno sequence, others do not. If one is not present in the plasmid, it must be introduced when the cDNA sequence is modified for introduction into the expression plasmid.

The Shine–Dalgarno sequence needs to be positioned in close proximity to the ATG. Ideally, the nucleotide that pairs with C1535 of the 16S RNA should be positioned eight nucleotides upstream of the A of the initiation codon, although a range of 4–14 nucleotides is tolerated (Gold *et al.*, 1981). If the Shine–Dalgarno sequence is supplied by the plasmid, the restriction enzyme recognition site used to join the cDNA to the plasmid must be quite close to the ATG. Expression systems have been developed in which the restriction site used for creating the expression system includes the initiator ATG. Many expression plasmids are available that have *Nde*I (CAT$\underline{\text{ATG}}$) or *Nco*I (CC$\underline{\text{ATG}}$G) recognition sites at the initiator ATG, which makes it possible to move only the coding region of the cDNA into the expression plasmid. Note, however, that if the *Nco*I site is used, retaining the *Nco*I site in the final construction specifies the first base of the second codon. This limits the choices for the second amino acid in the recombinant protein. *Nde*I does not have this limitation.

The termini of proteins influence their susceptibility to degradation by cellular proteases, most notably ClpA. The N-end rule for bacteria is that proteins in which the N-terminal amino acid is Phe, Leu, Trp, Tyr, Arg or Lys are unusually susceptible to proteolysis (Tobias *et al.*, 1991). (The stability of proteins beginning with Pro has not been determined.) These amino acids (as well as others) seem to impart instability in eukaryotic cells as well. Thus in most cases, if one is expressing intact proteins, the N-terminal amino acid of the native sequence will not generally present a problem. Furthermore, under most circumstances, generation of proteins with N-end-rule amino acids at their N-termini are unlikely, since all proteins are initiated with methionine, and while N-terminal methionines are sometimes removed, the specificity of *E. coli* aminopeptidase is such that methionines adjacent to N-end-rule amino acids are not removed with high efficiency (Hirel *et al.*, 1989). Note that methionine removal sometimes occurs, though to a lesser degree, if the penultimate residue is Asn, Asp, Leu or Ile. Thus, Leu residues should probably be avoided at the second position. It is also possible to generate termini containing N-end-rule amino acids by endoproteolytic cleavage; thus it might be advantageous to avoid these amino acids at the beginnings of proteins where unstructured ends are suspected.

Codon usage can influence expression levels. Although it is not something that should routinely be considered in the initial stages of a project, it is a factor that should be kept in mind if no or low levels of expression are observed. Although the genetic code is universal, it is also degenerate: twenty amino acids are specified by 61 codons. Most amino acids are specified by more than one codon; in many cases, some of the codons are used more often (and translated more efficiently) than others. Unfortunately, there are substantial differences in codon preference/usage in prokaryotes and eukaryotes (Zhang *et al.*, 1991). In *E. coli*, codon usage reflects the abundance of the cognate tRNA strands, and poorly expressed genes tend to contain a higher frequency of rare codons (De Boer & Kastelein, 1986). Although a number of theories have been proposed, prediction of the adverse effects of rare codons on the expression of any given sequence is not currently feasible. Factors such as the position of the codons, their clustering or dispersity and the RNA secondary structure may all contribute to levels of expression (Goldman *et al.*, 1995; Kane, 1995). In many instances, *E. coli* do make relatively large amounts of recombinant protein from mRNA strands that contain a number of rare codons (Ernst & Kawashima, 1988; Lee *et al.*, 1992). But in other cases, optimizing codon usage (Hernan *et al.*, 1992; Mohsen & Vockley, 1995) or co-expressing low abundance tRNAs (Brinkmann *et al.*, 1989; Del Tito *et al.*, 1995) has improved the level of expression of recombinant proteins. Since oligonucleotides 50–75 bases long can be synthesized relatively easily, it is possible to create relatively large synthetic cDNA strands or genes that have optimal codon usage. An alternative strategy is to take advantage of plasmids that have been constructed for co-expression of low abundance tRNA strands [$\text{tRNA}^{\text{Arg(AGA/AGG)}}$ and $\text{tRNA}^{\text{Ile(AUA)}}$] (Schenk *et al.*, 1995; Kim *et al.*, 1998). Fortunately, these strategies are not usually necessary; before attempting to optimize codon usage, one should first ask whether the natural sequence can be expressed efficiently.

Once plasmid constructs have been created and strains have been assembled, it is important that they be properly stored. Although it is possible to persuade *E. coli* to make large amounts of recombinant protein, it should be remembered that this is an artificial situation chosen by the investigator, not the *E. coli* host. As such, it behoves the experimentalist to pay careful attention to the host; *E. coli* have no *a priori* interest in what the experimentalist wants. All strains and plasmids should be carefully maintained using sterile techniques. Passage of bacterial stocks should be minimized, and master stocks should always be prepared when an expression clone is first isolated or received. The expression system can, in many cases, be successfully stored as a plasmid-containing strain, frozen as a glycerol stock (containing 15% glycerol) at −70 °C. However, it is best to also store the components separately – the expression plasmid as a DNA preparation, ideally as an ethanol precipitate at −20 °C, and the *E. coli* host strain as a frozen glycerol stock at −70 °C. As has already been discussed, changes in the host, as well as in the plasmid, can lead to a decrease in the amount of recombinant protein produced. This problem can be reduced by producing a freshly transformed bacteria stock to start a large-scale fermentation, and this is the reason some people prefer to store plasmid DNA rather than *E. coli* expression strains. It is important to remember that freshly transformed colonies should be restreaked onto selective plates before growth in liquid culture; this avoids the small background of cells not carrying plasmids that are present on the original transformation plates and that can cause problems in liquid cultures. Cells lacking plasmids generally have a faster growth rate and can survive in liquid cultures containing plasmid-carrying cells that express enzymes that degrade the antibiotics. Contamination by cells lacking plasmids can significantly reduce the yield of recombinant proteins.

Even with these precautions, it is important to remember that the *E. coli* host can modify the plasmid. Wild-type *E. coli* contain a number of recombination systems that can act on plasmid DNA. This is a particular problem if a plasmid contains repeated sequences. Recombination between direct repeats is quite efficient in wild-type *E. coli*, but is greatly reduced in *recA* strains. Most of the *E. coli* hosts commonly used for producing recombinant proteins are *recA* deficient, and the use of such strains is strongly recommended.

Fermentation is an especially important part of protein expression. Using an identical strain and plasmid, slight alterations in growth conditions can make a substantial difference in the yield of the desired protein. Ideally, it is preferable to grow large amounts of *E. coli* that contain (relative to the host proteins) large amounts of the desired recombinant protein. In fermentation, the experimentalist controls the media, the temperature of fermentation and, in a large fermenter, the aeration and stirring. In rich media, if the culture is taken to saturation in shake flasks, it is usually possible to produce 4–8 g of *E. coli* (wet weight) per litre; substantially higher cell densities can be obtained in fermenters. The amount of *E. coli* that can be produced in actual practice and, more importantly, the amount of the recombinant protein relative to the *E. coli* host proteins, are sensitive to all of the variables. Unfortunately, there are relatively few hard and fast rules. To make matters worse, when the scale of the fermentation is changed, it is often necessary to develop new fermentation conditions; this is a particular problem when the scale is changed from shake flasks to a fermenter. Developing optimum conditions for the production of a recombinant protein in a fermenter usually requires repeated trials with the fermenter; this is both time consuming and expensive. Fortunately, with many expression systems, sufficient yields can be obtained using shake flasks, and, in cases where a fermenter is required, it is usually possible to get satisfactory (if suboptimal) results without extensive experimentation.

As a general rule, more total *E. coli* and more recombinant protein can be obtained by growing cells in rich media than in minimal media. The cells grow faster in such media, and inductions, in general, are fast and efficient. In some cases, it is necessary to choose between conditions that produce more total *E. coli* and conditions that produce a higher relative yield of the desired recombinant protein. Of these two, the relative yield of the desired protein is the more important. In designing fermentation protocols, it helps to understand how the host organism works. For example, *E. coli* are subject to catabolite repression. Given a choice of two carbon sources, *E. coli* will concentrate on the preferred carbon source to the exclusion of the second. *E. coli* prefer glucose to lactose; if a *lac*-based expression system is used, it is a good idea to avoid using growth media that contain glucose. Good results can often be obtained with media rich in amino acids (2 × YT or superbroth without glucose). In general, vigorous aeration is helpful. Begin fermentation trials by putting a relatively small amount of broth in a shake flask. For volumes of 1–1.5 l, aeration is much more efficient in wide-bottomed Fernbach flasks, and use of Fernbach flasks improves the yield of cells. In most fermenters, oxygen levels can be monitored, and air and O_2 delivery can be regulated to provide optimal levels of oxygen.

Finding an optimal temperature for maximum production of soluble recombinant protein usually requires experimentation. *E. coli* grow faster at 37 °C than at lower temperatures, and if a high-level expression of soluble protein is obtained under such conditions, there is rarely any advantage in looking further. However, in some cases, the relative yield of a recombinant protein can be substantially increased by growing *E. coli* expression strains at temperatures below 37 °C (discussed further below).

When screening expression constructs for production of recombinant protein, four scenarios are most commonly encountered:

(1) high-level expression of soluble recombinant protein;
(2) high-level expression of the recombinant protein, with a greater or lesser proportion of the protein in inclusion bodies;
(3) no expression or very low levels of expression; and
(4) lysis of cells.

The first result is usually the most welcome. Occasionally however, the expressed protein is smaller than predicted, presumably due to proteolysis. In such cases, production of a stable fragment suggests the presence of a compact, folded domain which might be worth pursuing for crystallography. However, it should be noted that not all soluble proteins are properly folded. Occasionally, misfolded proteins are expressed at high levels in soluble form. Such proteins usually exhibit aberrant behaviour during purification, such as aggregation or precipitation, migration as broad peaks during column chromatography and elution in the void volume during size-exclusion chromatography. In such cases, additional experimentation is required. Inclusion bodies are usually the result of improper protein folding, and cell lysis generally indicates severe toxicity. There are two obvious reasons for a failure to produce measurable amounts of a recombinant protein: either there is a problem at the level of transcription and/or translation, or there is proteolytic degradation of the protein. Some potential solutions to these problems are discussed below.

In some cases, the stability of the recombinant protein is related to its solubility. In general, only well folded proteins are soluble at high concentrations. In all living cells, protein concentrations are high; if a recombinant protein is expressed at a high level, it will be present inside the host cell at a high concentration. Protein folding is an active process in living cells. Molecular chaperones are used both to prevent unwanted interactions with other partially folded proteins and to promote the folding process. In some cases, when a recombinant protein is expressed at high levels, it will not fold properly in *E. coli*, either because it fails to interact properly with *E. coli* chaperones, or because it is made at such high levels that it overwhelms the available chaperones. In such cases the unfolded and/or partially folded protein may aggregate in inclusion bodies (Mitraki & King, 1989), which is both a blessing and a curse. Proteins in inclusion bodies are essentially immune to proteolytic degradation. Additionally, it is usually relatively easy to obtain the inclusion bodies in relatively pure form, making it simple to purify the recombinant protein. Unfortunately, the recombinant protein obtained from the inclusion bodies must be refolded. There are a variety of protocols for refolding proteins (discussed in Section 3.1.5.3), but few simple, universal prescriptions. Even under the most favourable conditions, with proteins that refold easily and (relatively) efficiently, the yield of properly folded material is often low. For some recombinant proteins obtained from inclusion bodies, it is the efficiency of the refolding step that limits the amount of material that can be obtained for crystallization. We will discuss this issue in more detail in Section 3.1.5.3.

The formation of inclusion bodies is the result of aggregation of non-native proteins. Factors that alter the folding pathway and/or affect the concentrations of unfolded or misfolded proteins can have a dramatic influence on the yield of soluble protein. It is not uncommon for recombinant proteins that form inclusion bodies when expressed at high levels (such as in a T7 expression system) to be present at undetectable levels when expressed at slightly lower levels (such as from a constitutive *lac* promoter). Presumably, in both cases the protein is failing to fold rapidly and efficiently. In the former case, the high levels of unfolded intermediates lead to the formation of inclusion bodies; in the latter case, the concentration of the unfolded protein is not sufficient to form inclusion bodies, and the unfolded protein is degraded. In some cases, it is relatively easy to express the protein, but variations in expression systems and/or culture conditions result in quite different yields of soluble and insoluble protein. In all of these situations, it is appropriate to try a number of different expression systems, with the hope that different kinetics of transcription and/or translation may result in concentrations of intermediates in which protein folding is favoured relative to aggregation and/or degradation. In some cases, reducing the temperature of fermentation is helpful (Schein & Noteborn, 1988). In addition to affecting rates of transcription and/or translation, temperature also affects folding. There are numerous examples in the literature where low temperature was essential to the recovery of soluble recombinant protein; however, there does not seem to be a general solution: optimal conditions seem to vary with each protein. In many cases, reducing the temperature of growth from 37 to 30 °C has improved the yield of soluble protein. However, temperatures as low as 17 °C have been reported as optimal for expression of some recombinant proteins (Biswas *et al.*, 1997), and there are anecdotal reports which indicate that protein can be successfully expressed as low as 14 °C. At low temperatures, growth of *E. coli* is quite slow. In most cases, inducible expression systems are used. Cells are grown to mid-logarithmic phase at 37 °C, and are cooled to the desired temperature just prior to induction (Yonemoto *et al.*, 1998). Significantly longer post-induction times are required for high protein yields, and soluble protein expression should be assessed over a 24-hour period to determine optimal times for maximum yields.

The rapid and proper folding of the overexpressed protein appears to be one of the most important factors in achieving high yields of recombinant proteins in *E. coli*. Attempts have been made to improve *in vivo* folding by co-expression of chaperones and other proteins that might aid the folding process (Wall & Plückthun, 1995; Cole, 1996; Georgiou & Valax, 1996). Once again, the usefulness of these strategies appears to be specific for individual recombinant proteins, although some folding components appear to be more broadly useful than others (Yasukawa *et al.*, 1995). A variety of proteins, including GroEL and GroES, DnaK and DnaJ, chaperones cloned from the host organism for the recombinant protein, thioridazine, protein disulfide isomerases (PDIs) and disulfide-forming protein DsbA, have all been used with varying degrees of success in different systems. It is unlikely that co-expression of chaperones or other proteins will be useful in overcoming folding or stability problems in proteins that are inherently unstable (those made unstable by removal of other domains, those lacking essential post-translational modifications or those failing to form essential disulfide bonds in the reducing environment inside *E. coli*).

Proteolytic degradation is an active process in *E. coli*, and several strategies for minimizing proteolysis of recombinant proteins have been developed (Enfors, 1992; Murby *et al.*, 1996). These strategies include secretion of proteins to the periplasm or external media, engineering of proteins to remove proteolytic cleavage sites, growth at low temperature and other strategies to promote folding, such as use of fusion proteins and co-expression with chaperones. One popular strategy, which unfortunately appears to be more protein-specific than might be expected, involves the use of *E. coli* strains that have genetic defects in the known proteolytic degradation pathways (Gottesman, 1990). If the desired protein is rapidly degraded in *E. coli*, and fermentation at lower temperatures does not solve the problem, *E. coli* deg$^-$ (degradation) mutants can be tried. However, the proteolytic machinery in *E. coli* is quite complicated, and a number of deg$^-$ mutants are available. All of the deg$^-$ mutants are more difficult to work with than wild-type strains, and there is no guarantee that expressing a particular recombinant protein in any of the available deg$^-$ mutants will cause a substantial increase in the yield of the recombinant protein. For these reasons, deg$^-$ mutants are usually tried only as a last resort. In most cases, proteolysis indicates a problem with protein folding, and efforts to improve protein folding are generally more fruitful than efforts to minimize proteolysis.

We briefly touched on the issue of the potential toxicity (to the *E. coli* host) of recombinant proteins when discussing constitutive and inducible vector systems. In general, the greatest difficulties are encountered with membrane proteins and enzymes. For the most part, enzymes are a problem because their enzymatic activities derange the host cell. For example, proteases are notoriously difficult to produce in large amounts. There are several ways to address this problem. First, as has already been discussed, it is important to use a tightly controlled inducible system if the recombinant protein is likely to disturb the metabolism of the *E. coli* host profoundly. If the recombinant protein is not properly folded, and is present primarily in inclusion bodies, the degree of toxicity is less, and often much less, than if the recombinant protein is present primarily in an active, soluble form. Although it is not the preferred procedure, and is not usually necessary, it is also possible to mutate the recombinant protein to reduce (or eliminate) its toxicity. In cases where the desired product is an enzyme, the enzyme can be inactivated by altering the amino acids at the active site.

Additional problems are encountered when trying to produce recombinant proteins that would, in higher eukaryotes, either be bound to or pass through membranes. There are several problems: *E. coli* do not usually grow well if they have large amounts of foreign protein in their membrane; this problem is compounded by the fact that the rules for membrane signals and signal processing are different in *E. coli* and higher eukaryotes. In general, the solution to this issue has been to express, in *E. coli*, only the internal or the external domain of membrane proteins from higher eukaryotes. Not only does this usually solve the problem of the toxicity of the protein in *E. coli*, but domains that are not directly associated with the membrane are usually much more soluble, easier to purify and much better candidates for crystallization. There is an additional issue. In contrast to the cell interior, which is, in general, a reducing environment, the milieu outside the cell is usually an oxidizing environment. Many of the proteins found on the outside of higher eukaryotic cells, or proteins that are exported from higher eukaryotic cells, have disulfide bridges that help stabilize their secondary and/or tertiary structure. Such disulfide bonds do not ordinarily form properly inside *E. coli*, and it can be much more difficult to obtain recombinant proteins that have extensive and complex disulfide bridges in a properly folded form from *E. coli*.

3.1.4.2. *Yeast*

Yeasts are simple eukaryotic cells. Considerable effort has been expended in studying brewers' yeast, *Saccharomyces cerevisiae*, and in developing plasmid systems and expression vectors that can be used in this organism. Recently, methylotrophic yeasts, most notably *Pichia pastoris*, have been developed as alternative systems that offer several advantages over *S. cerevisiae*. Although yeast expression systems are reasonably robust, the expertise required to use these systems effectively is not as widespread as the corresponding expertise for the manipulation of *E. coli* strains. Nor are the tools, media and reagents necessary to grow yeast and select for the presence of expression plasmids as broadly available as those used for *E. coli* systems. However, the increasing commercial availability of complete kits (such as *Pichia* expression systems from Invitrogen) is making yeast systems more accessible.

While yeast systems do offer some advantages relative to *E. coli*, these advantages are, in general, modest. One primary advantage, the ability to produce large amounts of biomass using simple, inexpensive culture media, is probably more important for industrial-scale protein expression than for most laboratory applications, even those involving crystallography, which requires more protein than most simple biochemical experiments. Yeast systems do not, in general, offer solutions to some of the most difficult problems encountered when trying to express recombinant proteins in *E. coli.* Specifically, the problem of mimicking the post-translational modifications found in higher eukaryotes (particularly glycosylation), which has not been solved for *E. coli*, has not been solved in yeast either. None of the available systems recapitulates the post-translational modifications found in higher eukaryotes. Additionally, yeast systems introduce some new problems not seen with *E. coli* expression systems, specifically genetic instability and hyperglycosylation, both of which are more problematic in *S. cerevisiae* than in *Pichia*.

Yeast systems are perhaps most valued for high-level production of secreted proteins. For some naturally secreted proteins, passage through the secretory pathway is necessary for proteolytic maturation, glycosylation and/or disulfide bond formation and is essential for proper folding or function. But secretion is complex, and numerous factors, such as the signal sequence, gene copy number and host strain, can be critical for high-level expression. Secretion can significantly simplify purification, since secreted recombinant proteins can constitute as much as 80% of the protein in the culture medium. However, degradation of secreted proteins can be a major problem. In some instances, proteolysis has been minimized by alteration of the pH of the culture medium, by addition of amino acids and peptides, and by use of protease-deficient strains (Cregg *et al.*, 1993).

The rules for expression of proteins in yeast are not the same as those used either in *E. coli* or in higher eukaryotes. In yeast, as in *E. coli*, cDNA sequences from a higher eukaryote must be tailored for high-level expression, following rules that are fairly well understood. Yeast grows at 25–30 °C and has a slower growth rate than *E. coli* (under typical growth conditions, yeast has a doubling time of approximately 90 min, compared to 30 min for *E. coli*). Transformation of yeast can be achieved using competent cells, sphaeroplasts or electroporation, but by any technique it is less efficient than the transformation of *E. coli*. For these reasons, most yeast plasmids are designed to replicate both in *E. coli* and yeast; the DNA manipulations are done using an *E. coli* host, and the completed expression plasmid is introduced into yeast as the final step in the process.

Most expression vectors in *S. cerevisiae* are based on the yeast 2μ plasmid (Beggs, 1978; Broach, 1983) that is maintained as an episome, present at approximately 100 copies per cell. Plasmid instability can result in loss of expression during production, and integrating vectors have been developed that provide greater stability, albeit with levels of expression that are, in general, lower than the plasmid systems. Both constitutive and tightly regulated inducible expression systems have been developed using a variety of promoters. The most widely used systems involve galactose-regulated promoters, such as *GAL1*, which are capable of rapid and high-level induction. An extensive review of recombinant gene expression in yeast (Romanos *et al.*, 1992) is highly recommended as a resource for anyone seriously contemplating the expression of recombinant proteins in *S. cerevisiae.*

In terms of high-level expression, the *Pichia* system may ultimately prove to be more useful than *S. cerevisiae* (for reviews see Cregg *et al.*, 1993; Romanos, 1995; Hollenberg & Gellissen, 1997). There is considerable interest in developing the *Pichia* system for the expression of recombinant proteins, especially for industrial applications, and there has been sufficient progress made to support the publication of a useful monograph for specific techniques (Higgins & Cregg, 1998). *Pichia* offer several advantages over *S. cerevisiae*. Intracellular protein expression can be extremely high in *Pichia*, reaching grams per litre of cell culture. Large amounts of secreted proteins can be produced using media that are almost protein-free, although the expression levels are not quite as high as for intracellular proteins. *Pichia* can be cultured to very high cell density with good genetic stability. Additionally, hyperglycosylation is less of a problem in *Pichia*, which typically have shorter outer-chain mannose units (less than 30 outer-chain residues) than *S. cerevisiae* (greater than 50 residues) (Grinna & Tschopp, 1989).

Methylotrophic yeasts, which are able to use methanol as their sole carbon source, contain regulated methanol enzymes that can be induced to give extremely high levels of expression. In *Pichia* expression systems, the gene that encodes alcohol oxidase (*AOX1*) is most commonly used for the expression of foreign genes, but constitutive promoters are also available. Heterologous genes are inserted into vectors and then integrated into the *Pichia* genome, either duplicating or replacing (transplacement) the target gene, depending on how the linearized vector is constructed. High-level expression relies on integration of multiple copies of the foreign gene and, since this varies significantly, screening colonies to obtain clones with the highest levels of expression is required. Culture conditions and induction protocols are critical for optimal expression. Since *Pichia* are readily oxygen-limited in shake flasks, growth in fermenters is required for high-level expression (approximately five- to tenfold greater than in shake flasks).

Numerous factors make yeast expression systems significantly less straightforward than those of *E. coli*. In addition to the considerations mentioned above, it should be noted that yeast cells are surrounded by a tough cell wall and are therefore notoriously difficult to break. This makes the problem of purification of intracellular protein from yeast that much more difficult. Given the many complexities of expression in yeast, it is usually better to begin with an *E. coli* expression system and move to yeast only if the results obtained with *E. coli* systems are unacceptable. If yeast is used as an expression system, careful attention should be paid to maintaining defined stocks of the expression strain and the corresponding expression plasmids. Despite the availability of comprehensive kits, if the researcher does not have considerable experience with yeast, the enlistment of an experienced colleague is recommended.

3.1.4.3. Baculoviruses and insect cells

Baculovirus expression systems are becoming increasingly important tools for the production of recombinant proteins for X-ray crystallography. The insect cell–virus expression systems are more experimentally demanding than bacteria or yeast, but they offer several advantages. Expression of some mammalian proteins has been achieved in baculovirus when simpler expression systems have failed. Because insects are higher eukaryotes, many of the difficulties associated with expression of proteins from higher eukaryotes in *E. coli* do not apply: there is no need for a Shine–Dalgarno sequence, no major problems with codon usage and fewer problems with a lack of appropriate chaperones. Although glycosylation is not the same in insect and mammalian cells, in some cases it is close enough to be acceptable. In addition, for many crystallography projects, minimizing glycosylation is helpful, so that it may be more appropriate to modify the gene or protein to avoid glycosylation (or minimize it) than to try to find ways to recapitulate the glycosylation pattern found in mammalian cells. As is the general case in biotechnology, the development of baculovirus expression systems is work in progress. Progress has been made towards making recombinant proteins in insect cells with glycosylation patterns that match those in mammalian cells (reviewed by Jarvis *et al.*, 1998). Baculovirus systems allow expression of recombinant proteins at reasonable levels, typically ranging from 1–500 mg l^{-1} of cell culture. Considerable work has gone into the development of convenient transfer vectors, and baculovirus expression kits are available from more than ten different commercial sources.

Baculoviruses usually infect insects; in terms of the expression of foreign proteins, the important baculoviruses are the *Autographa californica* nuclear polyhedrosis virus (AcNPV) and the *Bombyx mori* nuclear polyhedrosis virus (BmNPV). AcNPV has been used more widely than BmNPV in cell-culture systems; the BmNPV virus is used primarily to express recombinant proteins in insect larvae. The advantage of BmNPV is that it grows well in larger insect larvae, making the task of harvesting the haemolymph easier. Proteins expressed for crystallography have all been, to the best of our knowledge, expressed using the AcNPV virus system; we will not discuss the BmNPV virus expression system here. Anyone wishing to learn more about either AcNPV or BmNPV is urged to consult two useful monographs: *Baculovirus Expression Protocols* (Richardson, 1995) and *Baculovirus Expression Vectors: A Laboratory Manual* (O'Reilly *et al.*, 1992). There are also shorter reviews that are quite helpful (Jones & Morikawa, 1996; Merrington *et al.*, 1997; Possee, 1997).

In nature, in the late stage of replication in insect larvae, nuclear polyhedrosis viruses produce an occluded form, in which the virions are encased in a crystalline protein matrix, polyhedrin. After the virus is released from the insect larvae, this proteinaceous coat protects the virus from the environment and is necessary for the propagation of the virus in its natural state. However, replication of the virus in cell culture does not require the formation of occlusion bodies. In tissue culture, the production of occlusion bodies is dispensable, and the primary protein, polyhedrin, is not required for replication. Cultured cells infected with wild-type AcNPV produce large amounts of polyhedrin; cells infected with modified AcNPV vectors, with other genes inserted in place of the polyhedrin gene (or in place of another highly expressed gene, *p10*, that is dispensable in cultured cells), can express impressive amounts of the recombinant protein.

The AcNVP genome is 128 kb, which is too large for convenient direct manipulations. In most cases, novel genes are put into the AcNPV genome by homologous recombination using transfer vectors. Transfer vectors are small bacterial plasmids that contain AcNPV sequences that allow homologous recombination to direct the insertion of the transfer vector into the desired place in the AcNPV genome (often, but not always, the polyhedrin gene). Originally, the purified circular DNA from AcNPV and the appropriate transfer plasmids were simply cotransfected onto monolayers of insect cells. Plaques develop, and if the insertion is targeted to the polyhedrin gene, plaques that contain viruses that retain the ability to make polyhedrin (those that contain the wild-type virus) can be distinguished in the microscope from plaques that do not. This technique works, but has been largely replaced by systems that make it easier to obtain and/or find the recombinant plaques. The AcNPV genome is circular; if the DNA is linearized, it will not produce a replicating virus unless the break is repaired. The repair process is facilitated by the presence of homologous DNA flanking the break. Systems have been set up to exploit this property to increase the efficiency of the generation of vectors that carry the desired insert. Basically, the genome of the AcNPV vector is modified so that there is a unique restriction site at the site where the transfer vector would insert. Linear AcNPV DNA is cotransfected with a transfer vector. This can produce stocks in which greater than 90% of the virus is recombinant. Systems have also been developed in which a DNA insert can be ligated directly into a linearized AcNPV genome. This protocol also produces a high yield of recombinant virus (Lu & Miller, 1996).

There are also a number of systems that allow either the selection or, more often, the ready identification of recombinant virus. The marker most commonly used for this purpose is β-galactosidase; a number of AcNPV vectors or transfer systems that make use of β-galactosidase are commercially available. Once a recombinant plaque is identified, it should be purified through multiple rounds of plaque purification to ensure that a homogeneous stock has been prepared. Several independent isolates should be prepared and each checked for expression of the desired protein.

There are several important things to consider when setting up the cell-culture system. Although most baculoviruses have a relatively restricted host range, and AcNPV was first isolated from alfalfa looper (*Autographa californica*), for the purpose of expressing foreign proteins, it is usually grown in cells of the fall armyworm (*Spodoptera frugiperda*) or the cabbage looper (*Trichoplusia ni*). The isolation and purification of the appropriate AcNPV vectors are usually done in monolayer cultures. In contrast, the production of large amounts of recombinant protein is usually done in suspension cultures. There is also the issue of whether or not to include fetal calf serum in the culture media. In theory, since the cells can be grown in serum-free media, which saves money and makes the subsequent purification of the recombinant protein simpler, serum-free culture is the appropriate choice. However, growing cells in serum-free media is a trickier proposition, and the cells are more sensitive to minor contaminants. As a general rule, high-level production of recombinant proteins using a baculovirus vector requires host cells that are growing rapidly; this is sometimes easier to achieve with serum-containing media. It is not always a simple matter to switch cells adapted to growth on plates to suspension culture, nor is it always easy to switch cells grown in the presence of serum to serum-free culture. Since the vector is a virus, it is usually more convenient to use cells adapted to different conditions than to try to adapt the cells. However, the relative yield of the recombinant protein will not necessarily be the same in different cells grown under different culture conditions.

Although baculoviruses, particularly AcNPV, are convenient vectors, the expression of the recombinant protein is carried out by the insect cell host. Baculovirus infection kills the host cell, so it is not possible to use baculoviruses to derive insect cell cultures that continuously express a recombinant protein. It is possible, however, to introduce DNA segments directly into insect cells and derive cell lines that stably express a recombinant protein; there are constitutive and inducible promoters that can be used in insect cell systems (McCarroll & King, 1997; Pfeifer, 1998). Basically, the protocols used to introduce DNA expression constructs into cultured insect cells are similar to those used in cultured mammalian cells ($CaPO_4$, electroporation, liposomes *etc.*), and similar selective protocols are used (G418, hygromycin, puromycin *etc.*).

Expression systems have been prepared based on baculovirus immediate early promoters and on cellular promoters, including the hsp70 promoter and metallothionein (McCarroll & King, 1997; Kwong *et al.*, 1998; Pfeifer, 1998). Insect cells are, in general, easier (and cheaper) to grow in culture than mammalian cells, although many of the problems that exist in mammalian cell culture also exist in insect cell culture. Relative to the baculovirus system, the use of stable insect cell lines not only allows the continuous culture of cells that contain the desired expression system (provided the expressed protein is not too toxic), it also permits the use of *Drosophila* cell lines, which appear to have some advantages for the high-level production of recombinant proteins.

Compared to bacteria or yeast cells, cells from higher eukaryotes are quite delicate, and considerable care must be taken in cell culture. The cells are subject to shear stress, which can be a problem in stirred and/or shaken cultures; some researchers use airlift fermenters to help alleviate the problem. Compared to yeast and bacterial cells, cultured cells grow relatively slowly and require rich media that will support the rapid growth of a wide variety of unwanted organisms, so special care must be taken to avoid contaminating the cultures. Antibiotics are commonly used; however, antibiotics will not, in general, prevent contamination with yeasts or moulds, which often cause the greatest problems. If the baculovirus system is used, then the cells and viruses are kept separate, and the cells are relatively standard reagents. If there is contamination, the contaminated cultures can be discarded and replaced with fresh cells (and viruses). Stable transformed insect cells that express a recombinant protein must be kept free of all contaminants. As is always the case, both cells and viruses should be carefully stored. Any useful recombinant baculovirus can be easily stored as DNA.

3.1.4.4. Mammalian cells

In some cases, however, even the baculovirus and/or insect cell expression systems are not able to make the desired recombinant protein product. If the recombinant protein is sufficiently important, it can be produced in cultured mammalian cells. Although biotechnology companies have demonstrated that it is feasible to produce kilograms of pure recombinant proteins using cultured mammalian cells, the effort required to produce tissue culture cells that express high levels of recombinant protein is substantial, and the costs of growing large amounts of tissue culture cells are beyond the means of all but the best-funded laboratories. To make matters worse, there are no well defined plasmids that reliably and stably replicate in mammalian cells. It may be possible to develop reliable episomal replication systems based on viral replicons; however, even the best developed viral episomes are still not entirely satisfactory (see, for example, Sclimenti & Calos, 1998). Cell lines are usually prepared by transfection; following transfection, some of the cells (usually a small percentage) will incorporate transfected DNA into their genomes. A number of agents can be used to transfect DNA; these include, but are not limited to, $CaPO_4$, DEAE Dextran, cationic lipids *etc.* This is a complex and poorly defined process; the transfected DNA is often incorporated into complex tandem arrays. Neither the amount of transfected DNA nor its location in the host genome is controlled in a standard transfection; as a consequence, the expression level varies substantially from one transfected cell to another. This makes the process of creating mammalian cell lines that efficiently and stably express a recombinant protein a labour-intensive process. Ordinarily, the DNA segment carrying the gene for the desired recombinant protein is linked to a selectable marker; selection for the marker is usually sufficient to cause the retention of the gene for the desired recombinant protein, provided that it is not toxic to the host cell. The tandem arrays produced by transfecting DNA into mammalian cells are often unstable. Recombination within the tandem array can decrease (or less commonly increase) the number of copies of the transfected gene. It is possible to take advantage of this instability. Selection protocols, which usually involve the DHFR gene and methotrexate, have been developed that can select for cells that have the DNA segments containing both the selectable marker and the gene for the desired recombinant protein in higher copy number (Kaufman, 1990); these can be used to develop cell lines that express high levels of the recombinant protein.

There are alternative methods that can be used to deliver an expression construct to a cultured mammalian cell. For example, the DNA can be introduced by electroporation, and homologous recombination can be used to embed an expression construct at a specific place in the host genome. However, such strategies, while in some ways more elegant than simple DNA transfection, do not appear to simplify the problem of creating a cell line that produces large amounts of a specific gene product. There are also a variety of viral vectors that can be used to introduce genes into cells either transiently or stably. At the time of writing, viral vector systems, which are extremely useful for studying the effects of expressing foreign genes in cultured mammalian cells, do not appear to offer any obvious advantages for the preparation of cultured cells that can express the relatively large amounts of recombinant protein needed for crystallography. However, this is an area where the research effort is particularly intense, so it is entirely possible that in the near future there will be a viral vector (or vectors) which will offer significant advantages for inducing high-level expression of recombinant proteins in cultured mammalian cells.

Until relatively recently, one of the primary problems in working with expression systems in cultured mammalian cells has been the lack of a tightly regulated inducible system. This has made the high-level expression of proteins that are deleterious to the growth of the cell an exceptionally difficult problem. The promoters originally used for inducible expression in cultured mammalian cells (metallothionein, glucocorticoid responsive *etc.*) tend to be leaky in the absence of the inducer. If cell lines were chosen in which the desired protein was not synthesized in the absence of the inducer, the level of the recombinant protein that could be made in the presence of the inducer was usually, but not always, low.

There has been progress in the development of more efficient and reliable inducible promoters for cultured mammalian cells. These systems are complex and require cell lines that express regulatory proteins not normally found in cultured mammalian cells. In this sense they are the logical counterparts of the T7 RNA polymerase/*lac* expression systems for *E. coli* already discussed in this chapter. The best developed of the engineered systems designed to permit the inducible expression of genes in mammalian cells are (1) the tetracycline system, (2) the F506/rapamycin system, (3) the RU486 system and (4) the ecdysone system (Saez *et al.*, 1997; Rossi & Blau, 1998).

Although these four inducible systems differ in important ways, there are common themes. Firstly, in all cases, the small molecule used as the inducer is not normally a regulator of gene expression in mammalian cells. This means that application of the inducer to cells should not substantially perturb the normal pattern of gene expression and, by implication, the health of the cells. Secondly, the DNA target sequences used to activate the expression of the recombinant gene/protein are not sequences known to be associated with the expression of normal cellular genes. This should also help prevent the activation of normal cellular genes when these systems are used.

In all of these systems, the specific regulation of an introduced gene requires a special regulatory protein that interacts with the appropriate small-molecule inducer and recognizes the requisite DNA target sequence that is linked to the gene of interest. These regulatory proteins, which were derived, at least in part, from regulatory proteins from nonmammalian hosts, must be present in the cell line for induction/regulation to occur. This means that either the researcher must choose from a relatively limited set of cells that already express the desired regulatory factor or face the problem of introducing (and carefully monitoring the proper expression and function of) both the regulatory factor and the desired recombinant protein. Considerable effort has been put into the development of each of these systems and significant progress has been made. At the moment, the tetracycline inducible system is probably the most fully developed; however, this is a fast moving area of research, and it is not now certain which of these systems will ultimately prove to be the most useful for the high-level expression of recombinant proteins in cultured mammalian cells.

Suffice it to say, however, that despite all the efforts of a large group of talented researchers, the systems available for use in cultured mammalian cells are much less well defined and much more difficult to use than the corresponding *E. coli* and yeast expression systems, and anyone who is not well versed in the problems associated with using expression systems designed for cultured mammalian cells should be most cautious about using them for the large-scale production of recombinant protein.

Despite these problems, mammalian (and, less frequently, insect cell) expression systems have been used to prepare proteins for crystallography. For example, in the recent determination of the X-ray structure of a complex between a portion of CD4, a modified version of HIV-1 gp120 and the Fab fragment of a monoclonal antibody, each of the proteins was made in cultured cells, but three different types of cultured cells were used. The two-domain segment of CD4 was made in Chinese hamster ovary cells. The monoclonal antibody used to prepare the Fab was made in an immortalized human B cell clone, and the core of gp120 in *Drosophila* Schneider 2 cells under the control of a metallothionein promoter (Kwong *et al.*, 1998).

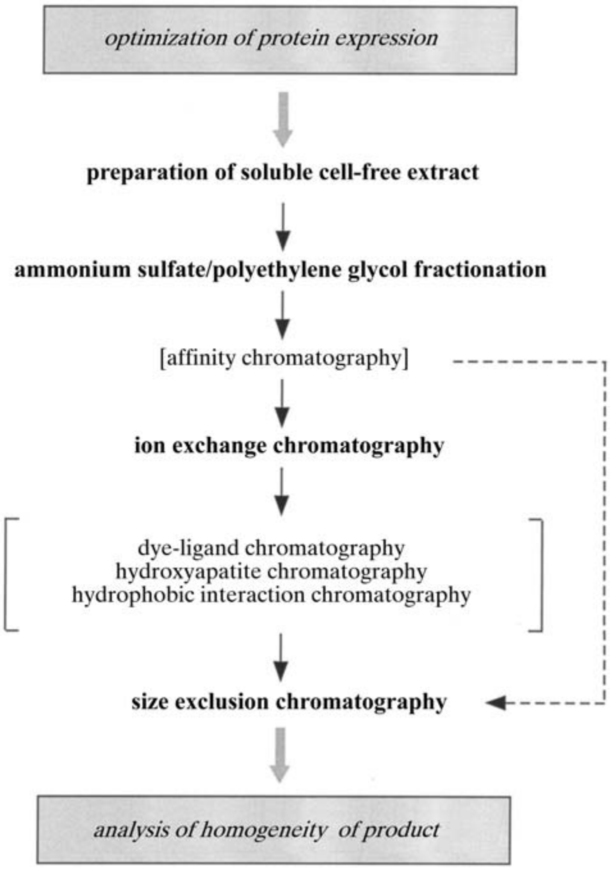
Tissue culture cells are much more difficult to grow than either yeast or *E. coli.* As has already been discussed in Section 3.1.4.3, there is the issue of using calf (or fetal calf) serum. A relatively small number of mammalian cell lines have been developed that will grow on defined media without serum; this is an advantage, but the media are still relatively costly. Mammalian cell lines expressing recombinant proteins must be maintained for long periods under carefully controlled conditions, both to ensure that the expression of the recombinant protein is maintained and to avoid contamination of the cultures with bacteria, yeast or moulds. Because the cells grow relatively slowly (doubling times are commonly 24–48 hours), it is usually not a simple task to produce 10–20 g (wet weight) of cells – something that can be done overnight with *E. coli.* If a useful cell line is obtained, it should be carefully stored in multiple aliquots. Cultured cells are routinely stored (in the presence of cryoprotectants) in liquid nitrogen. Short-term storage at −70 °C is an acceptable practice; however, long-term storage will be much more successful if lower temperatures are used.

3.1.5. Protein purification

3.1.5.1. Conventional protein purification

Those of us old enough to remember the task of purifying proteins from their natural sources, using conventional (as opposed to affinity) chromatography, where a 5000-fold purification was not unusual and the purifications routinely began with kilogram quantities (wet weight) of *E. coli* paste or calves' liver, are most grateful to those who developed efficient systems to express recombinant proteins. In most cases, it is possible to develop expression systems that limit the required purification to, at most, 20- to 50-fold, which vastly simplifies the purification procedure and concomitantly reduces the amount of starting material required to produce the 5–10 mg of pure protein needed to begin crystallization trials. This does not mean, however, that the process of purifying recombinant proteins is trivial. Fortunately, advances in chromatography media and instrumentation have improved both the speed and ease of protein purification. A wide variety of chromatography media (and prepacked columns) are commercially available, along with technical bulletins that provide detailed recommended protocols for their use. Purification systems (such as Pharmacia's FPLC and ÄKTA systems, PerSeptive Biosystems' BioCAD workstations and BioRad's BioLogic systems) include instruments for sample application, pumps for solvent delivery, columns, sample detection, fraction collection and information storage and output into a single integrated system, but such systems are relatively expensive. Several types of high capacity, high flow rate chromatography media and columns (for example, Pharmacia's HiTrap products and PerSeptive Biosystems' POROS Perfusion Chromatography products) have been developed and are marketed for use with these systems. However, the use of these media is not restricted to the integrated systems; they can be used effectively in conventional chromatography without the need for expensive instrumentation.

In designing a purification protocol, it is critically important that careful thought be given to the design of the protocol and to a proper ordering of the purification steps. In most cases, indi-



optimization of protein expression
preparation of soluble cell-free extract
ammonium sulfate/polyethylene glycol fractionation
[affinity chromatography]
ion exchange chromatography
dye-ligand chromatography
hydroxyapatite chromatography
hydrophobic interaction chromatography
size exclusion chromatography
analysis of homogeneity of product

Figure 3.1.5.1
Protein purification strategy. Purification of proteins expressed at reasonably high levels typically requires only a limited number of chromatographic steps. Additional chromatography columns (indicated in brackets) can be included as necessary. Affinity chromatography can allow efficient purification of fusion proteins or proteins with well defined ligand-binding domains.

vidual purification steps are worked out on a relatively small scale, and an overall purification scheme is developed based on an ordering of these independently developed steps. However, the experimentalist, in planning a purification scheme, should keep the amount of protein needed for the project firmly in mind. In general, crystallography takes a good deal more purified protein than conventional biochemical analyses. Scaling up a purification scheme is an art; however, it should be clear that purification steps that can be conveniently done in batch mode (precipitation steps) should be the earliest steps in a large-scale purification, chromatographic steps that involve the absorption and desorption of the protein from columns (ion-exchange, hydroxyapatite, hydrophobic interaction, dye-ligand and affinity chromatography) should be done as intermediate steps, and size exclusion, which requires the largest column volumes relative to the amount of protein to be purified, should generally be used only as the last step of purification. If reasonably good levels of expression can be achieved, most recombinant proteins can be purified using a relatively simple combination of the previously mentioned procedures (Fig. 3.1.5.1), requiring a limited number of column chromatography steps (generally two or three).

All protein purification steps are based on the fact that the biochemical properties of proteins differ: proteins are different sizes, have different surface charges and different hydrophobicity. With the exception of a small number of cases involving proteins that have unusual solubility characteristics, batch precipitation steps usually do not provide substantial increases in purity. However, precipitation is often used as the first step in a purification procedure, in part because it can be used to separate protein from nucleic acids. Nucleic acids are highly charged polyanions; the presence of nucleic acid in a protein extract can dramatically decrease the efficiency of column chromatography, for example by saturation of anion-exchange resins. If the desired protein binds to nucleic acids and the nucleic acids are not removed, ion-exchange chromatography can be compromised by the interactions of the protein and the nucleic acid and by the interactions of the nucleic acid and the column. The most commonly used precipitation reagents are ammonium sulfate and polyethylene glycols. With little effort, the defined range of these reagents needed to precipitate the protein of interest can be determined. However, if the precipitation range is broad, it may be only marginally less efficient simply to precipitate the majority of proteins by addition of ammonium sulfate to 85% saturation or 30% polyethylene glycol 6000. Precipitation can be a useful method for concentrating proteins at various steps during purification and for storing proteins that are unstable upon freezing or upon storage in solution.

Column chromatography steps in which the protein is absorbed onto the resin under one set of conditions and then eluted from the column under a different set of conditions can produce significant purification. Anion-exchange chromatography is usually a good starting point. Most proteins have acidic pIs, and conditions can often be found that allow binding of the protein to anion-exchange matrices. Elution of the protein in an optimized gradient often yields greater than tenfold purification. If conditions cannot be found under which the protein binds to an anion-exchange resin, a reverse strategy can be advantageous. Conditions can be adjusted to promote the binding of most proteins, yielding a flow-through fraction enriched for the protein of interest. Fewer proteins interact with cation-exchange resins; if the desired protein binds, this can be a powerful step. Use of an anion exchanger does not necessarily preclude use of a cation-exchange column; under appropriately chosen sets of conditions (most notably adjustment of pH), a single protein can bind to both resins. Hydroxyapatite resins provide a variation of ion-exchange chromatography that can be extremely powerful for some proteins. While hydroxyapatite columns (traditionally just a modified form of crystalline calcium phosphate) have the reputation of slow flow rates, alternative matrices exhibiting improved flow properties have made hydroxyapatite chromatography significantly less tedious. Hydrophobic interaction chromatography can also provide significant purification and has the advantage that the protein is loaded onto the resin in a high ionic strength buffer, making it a good step following ammonium sulfate precipitation. Proteins can behave very differently with different hydrophobic matrices, and an exploration of a variety of different resins is often a worthwhile exercise. Several tester kits containing an assortment of resins are commercially available. Dye-ligand chromatography can also be explored using an assortment of test columns. Several of the dyes, most notably Cibacron Blue F3GA, have structures that resemble nucleotides and have been useful in purifying kinases, polymerases and other nucleotide-binding proteins. However, many proteins have significant affinity for various dyes, independent of nucleotide-binding activity, and the usefulness of dye-ligand chromatography for any specific protein needs to be determined empirically.

Size-exclusion chromatography, which does not involve absorption of the protein onto the matrix, rarely provides as much purification as the chromatography steps described above.

However, this can be a good step to include at the end of a purification scheme. Isolation of a well defined peak in the included volume separates intact, properly folded protein from any damaged/aggregated species that may have been generated during the purification procedure. Furthermore, size-exclusion chromatography can provide a useful indication of whether the protein is a well defined, folded, compact, monodisperse population, or whether it is oligomerizing, aggregating or exists in an unfolded or extended form. Although size-exclusion chromatography does not provide a definitive analysis of such behaviour, migration of the protein consistent with its expected molecular weight is generally a good sign; elution of a relatively small protein in the void volume suggests a need for further analysis. Size-exclusion-chromatography media are available for the fractionation of proteins in many different size ranges. Substantial improvement in purification can be achieved by choosing a size range that is optimal for the protein of interest. However, the ability of size-exclusion columns to separate proteins of different molecular weights is dependent on the amount of protein loaded on to the column. Better purification is obtained when relatively small volumes of protein (generally 1–2% of the column bed volume) are loaded on size-exclusion columns. If really large amounts of protein are needed for a crystallography project, it can be difficult (and expensive) to set up size-exclusion columns large enough to fractionate the desired amount of protein.

3.1.5.2. Affinity purification

The most powerful purification steps are those that most clearly differentiate the desired protein from the other proteins present. Many proteins bind specifically to substrates, products and/or other proteins. In some cases, it is possible to use specific ligands to design columns to which the desired protein will bind selectively. For example, it may be possible to chemically link the substrate or product of a particular enzyme to an inert support. If the modification to the small molecule needed to link it to the support is chosen so that it does not interfere with the binding of the enzyme, the modified resin can be used to purify the protein by affinity chromatography. If, as expected, the desired protein binds selectively, it can usually be eluted by washing the column with the same substrate used to prepare the column. This is a powerful procedure and can produce greater than 100-fold purification in a single step. Although this is a fairly well developed field, and there is sufficient experience to show that the process is often fruitful, it must be said that the development of an efficient and effective affinity column and an attendant purification procedure can be long, difficult and, depending on the ligand and/or activated resin, sometimes expensive. In addition, the preparation of the column usually involves some moderately sophisticated chemistry; if such a step is contemplated, it is helpful to have the requisite chemical sophistication.

Immuno-affinity chromatography is a classic affinity method that uses affinity media created by coupling antibodies (either monoclonal or polyclonal) specific for the protein of interest to an activated resin. Theoretically, if good antibodies are available in sufficient quantity, this should be a powerful and widely applicable method. However, immuno-affinity chromatography has two severe limitations. In most cases, the interaction between the antibody and antigen is so tight that harsh conditions are necessary to elute the bound protein, potentially resulting in denaturation of the protein. Additionally, scaling up the procedure for isolation of 5–10 mg of protein is usually not feasible because of the large quantities of antibody required for column preparation.

Because the process of affinity chromatography is so powerful, and the development of a specific affinity column is difficult, considerable effort has been expended on the development of general procedures for affinity chromatography. As discussed previously, it is possible to modify the recombinant protein so that it contains a sequence element that can be used for affinity chromatography. Numerous systems are being marketed that pair vectors for creation of fusion proteins with appropriate resins for affinity purification. Examples of these fusion element–affinity resin pairs include His_6–Ni^{2+}-nitrilotriacetic acid, biotinylation-based epitopes–avidin, calmodulin-binding peptide–calmodulin, cellulose or chitin-binding domains–cellulose or chitin, glutathione S-transferase–glutathione, maltose-binding domain–amylose, protein A domains–IgG, ribonuclease A S-peptide–S-protein, streptavidin-binding peptides–streptavidin and thioredoxin–phenylarsine oxide.

Several considerations are important in choosing a strategy for expression and purification of a fusion protein. Some of these issues have already been discussed (see Section 3.1.3.3). The most fundamental, and unfortunately least predictable, is what construct will produce large amounts of the recombinant protein. The presence of fusion proteins and/or purification tags perturbs the recombinant protein to a greater or lesser degree. Perturbation can in some cases be beneficial, with the fusion protein aiding *in vivo* folding or *in vitro* refolding. There is also the issue of whether or not to remove the tag or fusion protein. Removal of the tag usually involves engineering a site for a specific protease, digestion with that protease and subsequent purification to isolate the final cleaved product. Additional issues should also be addressed. Most of the well developed systems allow for the elution of the fusion protein from the affinity resin under relatively mild conditions that should not harm most proteins. However, the method of elution should be considered with respect to the specific requirements of the protein of interest. Since the costs of using the different systems on a large scale varies significantly, it is wise to calculate the expense associated with scaling up, allowing for the cost and lifetime of the affinity resin, the cost of the reagent used for elution and the cost of the protease if the tag is to be removed. Finally, the nature of the fusion element–affinity resin interaction should be considered. Some of these systems, such as the His_6 tag, can be used for purification under denaturing conditions, which is a considerable advantage if the desired recombinant protein is found in inclusion bodies.

3.1.5.3. Purifying and refolding denatured proteins

As we have already discussed, expressing high levels of recombinant prokaryotic or eukaryotic proteins in *E. coli* can lead to the production of improperly folded material that aggregates to form insoluble inclusion bodies (Marston, 1986; Krueger *et al.*, 1989; Mitraki & King, 1989; Hockney, 1994). Inclusion bodies can usually be recovered relatively easily, following lysis of cells by low-speed centrifugation (5 min at 12 000 *g*); inclusion bodies are larger than most macromolecular structures found in *E. coli* and denser than *E. coli* membranes. Care should be taken to achieve complete lysis, since an intact bacterial cell that remains after lysis will co-sediment with the inclusion bodies. In most (but not all) cases, the inclusion bodies contain the desired recombinant protein in relatively pure form.

In such cases, the problem lies not with the purification of the protein, but in finding a proper way to refold it.

Various general procedures for refolding proteins from inclusion bodies have been described (Fischer *et al.*, 1993; Werner *et al.*, 1994; Hofmann *et al.*, 1995; Guise *et al.*, 1996; De Bernardez Clark, 1998), and the literature is filled with examples of specific protocols. The insoluble inclusion bodies are usually solubilized in a powerful chaotropic agent like guanidine hydrochloride or urea. In general, detergents are not recommended. The denaturant is sequentially removed by dilution, dialysis or filtration. Both rapid dilution and slow removal of the denaturant have been used successfully. In most refolding protocols, relatively dilute solutions of the protein are used to avoid protein–protein interactions, and, if necessary, glutathione or some other thiol reagent is included in the buffer to accelerate correct pairing of disulfides. After a refolding procedure, the properly folded soluble protein must be separated from the fraction that did not fold appropriately. Improperly refolded proteins are relatively insoluble and can usually be removed by centrifugation. It is sometimes profitable to try to refold the recovered insoluble material a second time.

Once soluble protein has been obtained, conventional purification procedures may be employed. It should be noted that recovery of soluble protein is not necessarily an indication that the protein exists in a native state. Quantitative assays of protein activity should be used to characterize the protein, if such assays exist. Alternatively, the behaviour of the refolded protein should be critically assessed during subsequent purification steps; an improperly folded protein will be prone to aggregation, will generally give broad and/or trailing peaks during column chromatography and will migrate faster than expected during size-exclusion chromatography. Some proteins are more amenable to refolding than others. As has already been pointed out, if a protein has a complex array of disulfide bonds, it is usually more difficult to refold than a protein without disulfide bonds. Greater success in refolding is generally obtained with proteins composed of single domains than with multidomain proteins.

3.1.6. Characterization of the purified product

3.1.6.1. Assessment of sample homogeneity

The ultimate test of the usefulness of a purified protein for crystallization is determined by the actual crystallization trials. However, before such trials begin, the properties and purity of the recombinant protein should be carefully checked. There is some disagreement about the degree of purity required for crystallization. In the earliest days of protein purification, crystallization was used as a technique for the purification of proteins, and it is clear that absolute purity is not a requirement for the preparation of useful protein crystals. However, most practitioners of the art of crystallization prefer to use highly purified proteins for crystallization trials. There are several reasons for this. It is easier to achieve the high concentrations of protein (greater than 10 mg ml^{-1}) usually needed for crystallization if the protein is pure, and the behaviour of highly purified proteins is more reproducible. A homogeneous preparation of protein will precipitate at a specific point rather than over a broad range of solution conditions. Furthermore, degradation during storage and/or crystallization is minimized if all of the proteases have been removed.

Although there are a number of ways to check the purity of a protein, the most convenient, and widely used, involve electrophoresis. Most experimentalists use SDS–PAGE and/or isoelectric focusing to determine the purity and homogeneity of the protein. SDS–PAGE may be slightly more convenient for the detection of unrelated proteins; isoelectric focusing is probably more useful in detecting subspecies of the recombinant protein of interest. We will consider the nature and origins of such subspecies below. Once the protein(s) is fractionated, either on an isoelectric focusing gel or on SDS–PAGE, it is detected by staining, either with silver or with Coomassie brilliant blue. Neither reagent reacts uniformly with all proteins; depending on the proteins involved, either method can overestimate or underestimate the level of a contaminant relative to the desired recombinant protein. Silver staining is the more sensitive method. However, if there is sufficient material for a serious attempt at crystallography, the sensitivity of Coomassie staining is usually more than sufficient for analytical purposes. It is often useful to fractionate a protein preparation by both isoelectric focusing and SDS–PAGE, and stain gels with silver and Coomassie brilliant blue. This increases the chance of discovery of an important contaminant and/or heterogeneity in the protein preparation.

If the preparation is relatively free of unrelated proteins, but there is concern about the presence of multiple species of the desired recombinant protein, there are several techniques that can be applied. Mass spectrometry is capable of detecting small differences in molecular weights, and for proteins up to several hundred amino acids in length it is usually able to detect differences in mass equivalent to a single amino acid. This can be useful in detecting heterogeneity in post-translational modifications, if such are present, and in detecting heterogeneity at both the amino and carboxyl termini. Amino-terminal sequencing can also be used to detect N-terminal heterogeneity, but has some limitations that are discussed below.

In *E. coli*, the methionine used to initiate translation is modified with a formyl group. The formyl group, and sometimes the amino-terminal methionine, is removed from proteins expressed in *E. coli*. Removal of the N-terminal amino acid is dependent on the identity of the second amino acid; methionines preceding small amino acids (Ala, Ser, Gly, Pro, Thr, Val) are generally removed (Waller, 1963; Tsunasawa *et al.*, 1985). However, when large amounts of a recombinant protein are made in *E. coli*, the formylase and aminopeptidase that mediate N-terminal processing are sometimes overwhelmed, and removal of the N-terminal groups is often incomplete. It is common to observe heterogeneity at the amino termini of even the most highly purified recombinant proteins. Amino-terminal sequencing can be used to detect this type of amino-terminal heterogeneity; however, the portion of the protein that retains the formyl group will not be detected by this method, and a misleading impression of the quantity and quality of the protein preparation can be obtained.

Heterogeneity at both the amino and carboxyl termini can be introduced by proteolysis, especially when the ends of the protein are extended and unstructured. This problem is frequently encountered when domains (rather than intact proteins) are expressed and can often be avoided if the boundaries of compact structural domains are precisely defined. In addition to introducing heterogeneity due to partial proteolysis, dangling ends can contribute to aggregation.

In terms of crystallization, the ability to produce a highly concentrated monodisperse protein preparation is probably more important than absolute purity. There are a number of techniques that can be used to determine whether or not the protein is aggregating. Analytical ultracentrifugation is the classical method, and size-exclusion chromatography has been widely used, particularly by biochemists. However, many crystallographers routinely use dynamic light scattering to check concentrated protein preparations for aggregation (Ferré-D'Amaré & Burley, 1994). The method is relatively simple, very sensitive to small amounts of aggregation and has the additional advantage that it does not consume the sample. After testing, the sample (which is often precious) can still be used for crystallization trials.

If sample heterogeneity is detected, one is faced with the issue of whether it will adversely affect crystallization, and if so, how to remove it. Unfortunately, there do not seem to be general rules. Heterogeneity at the termini of proteins is a common occurrence. In many crystal structures, the termini are disordered and heterogeneity at these unstructured ends would not be expected to be a significant problem. Indeed, in a number of instances, N-terminal sequence analysis of proteins obtained by dissolving crystals has indicated substantial heterogeneity. However, in other cases, properly defined domain boundaries are thought to have been a critical factor in obtaining useful crystals. Domain boundaries can be determined by a combination of limited proteolysis, followed by identification of the fragments using mass spectrometry (Cohen *et al.*, 1995; Hubbard, 1998). Subsequent re-engineering of expression constructs with modified termini is a relatively easy task. Similar engineering can also be used to alter internal sequences, such as removal of sites of post-translational modification or introduction of mutations that improve solubility (Chapter 4.3).

3.1.6.2. Protein storage

Even when the efforts of those engaged in crystallization and those engaged in producing the desired recombinant protein are well coordinated, it is not usually appropriate or desirable to use all the available protein for crystallization at the same time. This means that some of the material must be stored for later use. Even under the best of circumstances, protein solutions are subject to a number of unwanted events that can include, but are not limited to, oxidation, racemization, deamination, denaturation, proteolysis and aggregation. As a general rule, it is better to store proteins as highly purified concentrated solutions. This reduces problems of proteolysis (since the proteases have been removed), and, in general, proteins are better behaved if they are relatively concentrated (greater than 1 mg ml^{-1}). This is not an absolute rule, however; if there are problems with aggregation, these can sometimes be minimized by storage of proteins in dilute solutions, followed by concentration of the samples immediately prior to crystallization. If the protein contains oxidizable sulfurs (free cysteines are a particular problem), reducing agents can be added (and should be refreshed as necessary), and the solutions held in a non-reducing (N_2) atmosphere. In some cases, it is easier to mutate surface cysteines to produce a more stable protein (see Chapter 4.3).

In general, proteins behave best under conditions of pH and ionic strength similar to those they would experience in the normal host. Usually this means a pH near, or slightly above, neutral and intermediate ionic strength. These conditions are often not the ideal conditions for crystallization, and dialysis or other forms of buffer exchange may be required before beginning crystallization trials. In general, protein solutions are stored either at 4 °C in a cold room or refrigerator, or at 0 °C on ice. It is essential that the protein be stored in a manner that will not allow microbial growth, usually achieved by sterilization of the protein solution by filtration through 0.2 micron filters and/or addition of antimicrobial agents, such as NaN_3. For long-term storage (periods longer than a few weeks), protein solutions are often precipitated in ammonium sulfate or frozen at either −20 or −70 °C. Repeated freezing and thawing is not recommended; if a protein sample is to be frozen, it should be divided into aliquots small enough so that each will be thawed only once. Whenever a protein sample is frozen and thawed, some loss of quality and/or activity can be expected. Freezing samples of intermediate concentration (1–3 mg ml^{-1}) usually works better than freezing either extremely dilute or concentrated samples. Cryoprotective agents can be added to protein samples destined to be frozen; however, it should be remembered that the same reagents that are helpful when freezing a protein sample may be distinctly unhelpful when that sample is thawed and used for crystallography. Most biochemists willingly add glycerol to their protein samples before freezing; crystallographers are not usually happy to find that their protein sample is dissolved in 50% glycerol. Both pH and ionic strength can affect a protein's tolerance to freezing and thawing. In many cases, buffer exchange and concentration procedures need to be performed to convert stored protein solutions to ones suitable for crystallization.

As is so often true in science, decisions about whether to freeze a particular protein sample and, if it is to be frozen, exactly how the freezing should be done, depend on experience. If the protein in question is an enzyme, it is often useful to set up a series of trials in which small aliquots of the protein are stored under a variety of conditions. If the aliquots are tested on a fairly regular basis, how stable the protein is in solution can usually be determined, as well as how well it will tolerate a cycle of freezing and thawing, with or without an added cryoprotectant. If enzyme assays are not available, other methods of characterization, such as gel electrophoresis, mass spectrometry and light scattering, can be used to check for degradation, oxidation of cysteines and aggregation. Armed with this information, and with a plan for how the protein will be used for crystallization, it is usually a fairly simple matter to decide whether or not to freeze a particular sample, and, if the sample is to be frozen, how best to do it. It is a good idea to make such tests early in a major crystallization effort. This will avoid the awkward dilemma that occurs when a large amount of a highly purified protein is available, and the knowledge of how best to store it is not.

3.1.7. Reprise

We have reached a point where it is possible to use recombinant DNA techniques to produce most proteins in quantities sufficient for crystallography. Both high-level expression systems and methods for making defined modifications of recombinant proteins vastly simplify the process of purification. This has played a direct and critical role in the ability of crystallographers to produce an astonishing array of new and exciting protein structures. We are beginning to come to grips with the next level of the problem: using the ability to modify the sequence of proteins to improve their crystallization properties. This is a difficult problem; however, there are already notable, if hard won, successes. It would appear that the marriage of genetic engineering and crystallography – clearly a case in which opposites attract – has been a happy union. This is entirely for the good. Collaborations between specialists in these disciplines have led to the solution of problems too difficult for any individual armed only with the skills of one or the other partner. It is important that genetic engineering be fully integrated into future crystallographic efforts, either directly within the crystallography laboratory or through close collaborations. There yet remain formidable problems in protein structure and function that will require all the combined talents of the most skilled practitioners of these arcane arts.

Chapter 3.2. Expression and purification of membrane proteins for structural studies

J. A. Ernst, D. G. Yansura and C. M. Koth

3.2.1. Introduction

Integral membrane proteins constitute about a third of the proteome of most organisms but less than 1% of all entries in protein structural databases (Berman *et al.*, 2002). This disparity is largely due to inherent difficulties in their expression, solubilization and purification. The production of sufficient protein for structural studies can be challenging for any target, but several obstacles are unique to membrane proteins. For example, proper insertion into the membrane relies on host cellular machinery that may be limiting or incompatible. Exceeding this capacity can lead to cell death or the accumulation of aggregated and inactive protein within the cell (Geertsma *et al.*, 2008). Also, post-translational modifications such as glycosylation, acylation and sulfation may not be faithfully reproduced (Grisshammer & Tate, 1995). As a further complication, even if sufficient expression can be achieved, most membrane-protein structural studies require that the target be extracted from the cellular membrane using detergents. However, detergents can adversely affect protein structure and function, as well as influence the outcome of crystal trials (Engel *et al.*, 2002; Lemieux *et al.*, 2003; Prive, 2007). Fortunately, if a strategy for purifying sufficient quantities of a given membrane-protein target *can* be established, crystallization strategies largely mimic the standard techniques for soluble proteins (Newby *et al.*, 2009).

Despite the aforementioned challenges, high-resolution structures of almost 200 unique membrane proteins have now been solved (http://blanco.biomol.uci.edu/Membrane_Proteins_xtal.html), the vast majority using protein produced by recombinant methods (Willis & Koth, 2008). The rate of new structure determinations has also increased dramatically over the last few years, mimicking the exponential growth of soluble protein structures in the early 1980s. Space limitations here preclude a thorough review of all possible membrane-protein production methods. However, an examination of the successful expression, solubilization and purification strategies that have led to membrane-protein structures reveals that, in many cases, remarkably similar methods have been used (Carpenter *et al.*, 2008; Willis & Koth, 2008; Newby *et al.*, 2009). Guided by these methods, the following sections detail a rational and consensus 'first-attempt' strategy that has worked for a broad range of membrane targets with only minor variations in technique (Dobrovetsky *et al.*, 2005, 2007; Lunin *et al.*, 2006). It must be noted that while this represents an evidence-guided approach, the methods provided herein will not work for every membrane protein and, in fact, will fail for many. Thus, prioritized lists of alternative strategies are provided for those targets in which the initial expression or isolation attempts do not succeed or problems are encountered.

3.2.2. A consensus strategy for membrane-protein expression

Historically, the likelihood of successful structure determination has been high for those membrane proteins that can be isolated from readily available abundant natural sources (Sakai & Tsukihara, 1998). Unfortunately, most membrane proteins do not meet this criterion. In reality, the vast majority of high-resolution membrane-protein structures are of prokaryotic targets, expressed in *Escherichia coli* by recombinant methods (Willis & Koth, 2008; Newby *et al.*, 2009). The reasons for this are simple. Attempting recombinant expression in *E. coli* is inexpensive, flexible, simple and easily scaled-up, and many constructs and strains can be screened quickly. As with crystallographic efforts for many soluble proteins (Gräslund *et al.*, 2008), most successful membrane-protein endeavours also commonly screen multiple constructs and/or orthologues for any given target (see, for example, Chang *et al.*, 1998; Doyle *et al.*, 1998), since the greater the number of unique constructs screened, the greater the chance that one will be successfully isolated and crystallized. Given the overwhelming use of *E. coli* for successful membrane-protein structures, a 'first-pass' expression strategy suitable for almost any membrane protein is clear: attempt expression in *E. coli* and, whenever possible, screen multiple constructs, orthologues and strains.

3.2.2.1. *Choosing the expression system and affinity tags*

In addition to the choice of expression host, one must also consider the expression system and the type and placement of affinity tags or fusion proteins. For *E. coli*, IPTG-inducible T7 polymerase-driven expression systems, such as those based on pET vectors (Studier & Moffatt, 1986) and λDE3 lysogen strains, are the most widely used for membrane proteins, as is the case for soluble targets. Also, it has generally been observed that for most targets, protein expression is optimal at lower temperatures (*i.e.* <20 °C; Christendat *et al.*, 2000; Wang *et al.*, 2003; Dobrovetsky *et al.*, 2005). When structural studies are the desired outcome, the most common tagging strategy for membrane proteins is to engineer a stretch of at least six histidine residues at the amino or carboxyl terminus of the target constructs; this is used for >80% of successful targets (Willis & Koth, 2008). If expression levels are sufficient (*i.e.* ≥ 0.05 mg g^{-1} cell paste), this often permits purification using a general two-step procedure: capture of the tagged protein by immobilized metal affinity chromatography (IMAC), followed by size-exclusion chromatography (SEC) (see below). Remarkably, this basic approach has proved successful for the crystallization of many membrane proteins, as discussed in the following section. If premature termination is observed during expression, the engineering of a carboxyl-terminal tag will ensure that these proteins are not isolated during purification. Also, extending the stretch of histidines to greater than six residues can improve the retention of membrane proteins on immobilized metal affinity resins. This can prove particularly useful, given the modest expression levels and reduced chromatographic resolution and recovery of many membrane targets (Dobrovetsky *et al.*, 2005; Eshaghi *et al.*, 2005; Surade *et al.*, 2006; Lewinson *et al.*, 2008). Other affinity tags are viable options, but are more rarely used. For example, although fusion proteins such as glutathione S-transferase (GST) and thioredoxin are widely used to promote expression and/or simplify the purification of soluble proteins [for an extensive comparison of various affinity tags, see Lichty *et al.* (2005)], they are rarely cited in expression strategies for polytopic membrane proteins.

Table 3.2.2.1

Strategies for improving recombinant membrane-protein expression in *E. coli*

Troubleshooting expression problems: if the 'first-pass' expression strategy is unsuccessful, then some changes in the expression construct, host strain or induction conditions may be helpful. The symptoms of the problem often give a clue as to how to make these corrections.

Symptom	Solution
E. coli colonies small after transformation into expression strain	Need tighter promoter such as phoA, araC *etc.*
Unprocessed signal sequence†	If none is used in native situation, remove from construct† If one is present in native situation, use an expression host co-translational signal sequence† If still unprocessed, lower translation initiation strength
Mostly high-molecular-weight aggregates	Decrease induction time
Rapid cell growth after induction with low expression levels	Increase translation initiation strength
Poor cell growth after induction with low expression levels	
(*a*) Accumulation maximum after only 1–3 h	Decrease translation initiation rates or plasmid copy number
(*b*) Accumulation increases out to 8–10 h post induction	Usually successful: (*a*) Re-synthesize the gene, removing rare codons and optimizing codon pairs† (*b*) Convert transmembrane and intracellular domain cysteines (normally reduced) to serines† (*c*) Try different non-DE3 lysogen strains after switching to a non-T7 promoter (i) Cytoplasmic protease deletions (ii) Periplasmic protease deletions (iii) Heat-shock htpR^{TS} Sometimes successful: (*a*) Try different C-terminal tags such as poly-his, Flag *etc.*† (*b*) Try different temperatures of induction such as 20, 25, 30 °C

† These methods are also useful for optimizing eukaryotic gene expression.

3.2.2.2. Strategies for improving membrane-protein expression

Low expression levels are common for many membrane proteins. Before testing alternative hosts, it may be worthwhile first to screen alternative *E. coli* expression systems, such as those using the tightly controlled arabinose promoter (Guzman *et al.*, 1995). Also, other *E. coli* strains can be tested. For example, the mutant C41 and C43 'Walker' expression strains (Miroux & Walker, 1996; Wagner *et al.*, 2008) yield higher expression levels for some membrane proteins. Table 3.2.2.1 summarizes common strategies for improving the expression of membrane proteins in *E. coli*. If reasonable efforts in *E. coli* still do not yield sufficient expression, then an alternative expression host should be considered. The next most successful is yeast. Of the 22 recombinant eukaryotic membrane proteins whose structures have been solved by crystallography, half were produced using *Pichia pastoris* (seven targets), *Saccharomyces cerevisiae* (three targets) or *Saccharomyces pombe* (one target) (Raman *et al.*, 2006). Membrane proteins expressed in yeast are typically fused to an amino-terminal host signal sequence to promote proper membrane targeting. The use of higher eukaryotic hosts, such as insect and mammalian cells, is also increasing as more groups attempt to crystallize recombinant eukaryotic targets. The recent high-resolution structures of several G-protein-coupled receptors are notable examples of targets expressed successfully in insect cells (Cherezov *et al.*, 2007; Rasmussen *et al.*, 2007; Hanson *et al.*, 2008; Jaakola *et al.*, 2008; Warne *et al.*, 2008).

To date, there is only one report of a structure determined from cell-free synthesis of the target membrane protein (EmrE; Chen *et al.*, 2007). However, for several reasons, cell-free approaches should be explored as a complement to traditional expression methods. Firstly, the absence of a host cell negates toxicity problems for some target proteins. Secondly, many targets that do not express in cells can be produced cell-free (Ishihara *et al.*, 2005; Klammt *et al.*, 2007; Savage *et al.*, 2007). Thirdly, these systems allow for considerable flexibility with respect to reaction conditions and components. Cell-free systems for prokaryotic and eukaryotic hosts have been described (Schwarz *et al.*, 2008), some of which function in the presence of solubilizing detergents (Ishihara *et al.*, 2005; Klammt *et al.*, 2007; Savage *et al.*, 2007) or lipids (Kuruma *et al.*, 2005; Schwarz *et al.*, 2007), facilitating proper folding and downstream purification of membrane-protein targets.

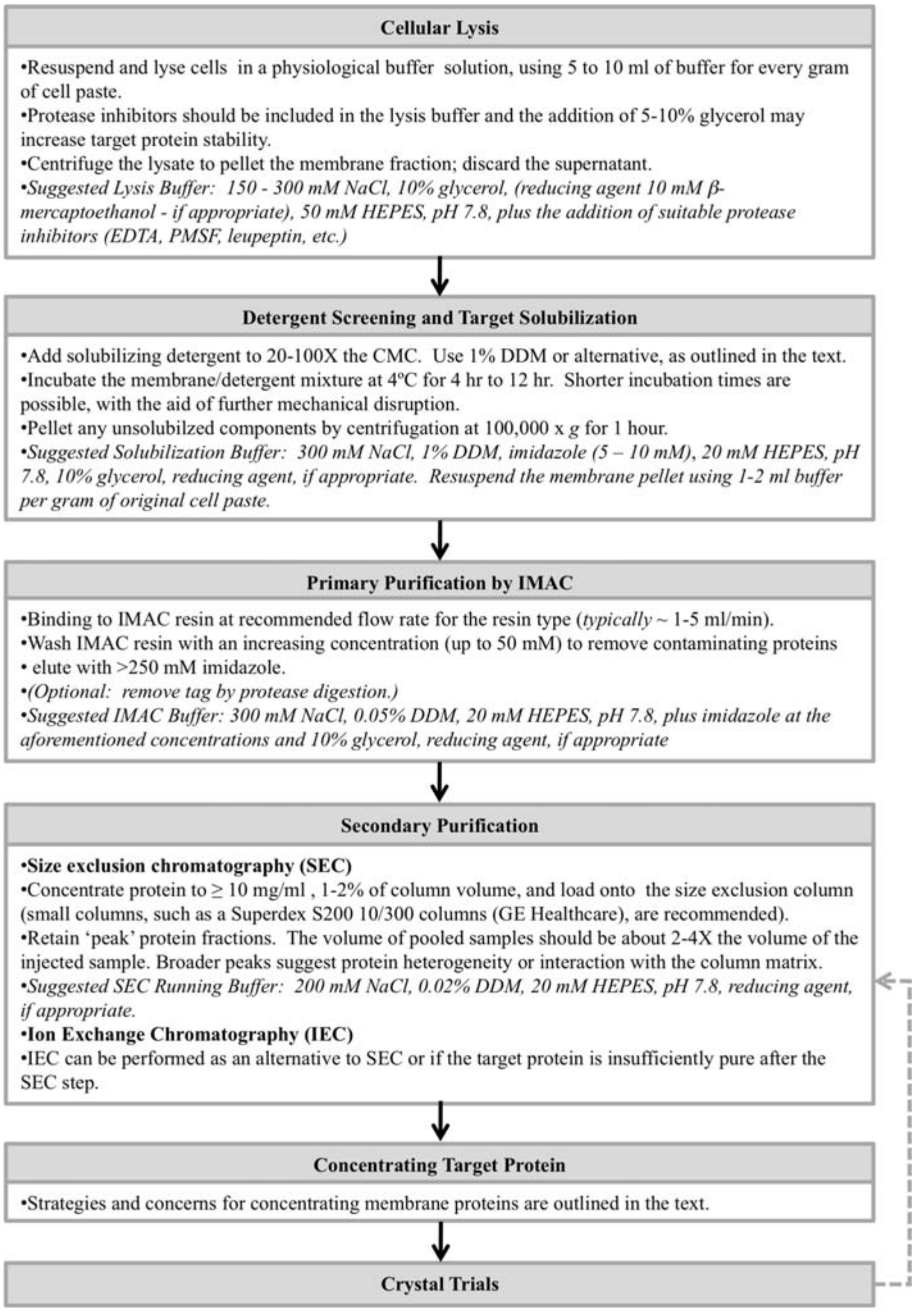
Many eukaryotic proteins have undergone extensive construct engineering to improve expression and/or crystallization outcomes. These include fusion to T4 lysozyme, mutation of glycosylation sites, deletion of potentially disordered regions and/or targeted evolution to identify conformationally stable mutants (Long *et al.*, 2005; Cherezov *et al.*, 2007; Rosenbaum *et al.*, 2007; Jaakola *et al.*, 2008; Magnani *et al.*, 2008; Serrano-Vega *et al.*, 2008; Warne *et al.*, 2009). Also worth mentioning is the observation that incorporation of an amino-terminal 'rhodopsin tag' comprising the first 20 amino acids of bovine rhodopsin (amino-acid sequence MNGTEGPNFYVPFSNKTGVV) has been found to boost dramatically the expression levels of eukaryotic membrane targets expressed in insect and mammalian cells (Krautwurst *et al.*, 1998).

3.2.3. A consensus strategy for membrane-protein purification

3.2.3.1. General principles

The purification of an expressed integral membrane protein for structural studies typically involves four discrete steps: cell lysis, membrane isolation, detergent extraction and chromatographic separation. In this section, an evidence-based consensus strategy is outlined which aims to serve as a starting point for membrane-protein purification. Detailed protocols are outlined in Fig.

3.2.3.1. Note that the most significant complication in this process is the need to use detergents in all steps of protein handling and chromatography. Detergents permit the extraction of target proteins from the membrane, but they must also maintain protein stability and activity by mimicking, as closely as possible, the lipid bilayer. Although many detergents do meet these criteria, relatively few are compatible with high-resolution structural studies.



Cellular Lysis

- •Resuspend and lyse cells in a physiological buffer solution, using 5 to 10 ml of buffer for every gram of cell paste.
- •Protease inhibitors should be included in the lysis buffer and the addition of 5-10% glycerol may increase target protein stability.
- •Centrifuge the lysate to pellet the membrane fraction; discard the supernatant.
- •*Suggested Lysis Buffer: 150 - 300 mM NaCl, 10% glycerol, (reducing agent 10 mM β-mercaptoethanol - if appropriate), 50 mM HEPES, pH 7.8, plus the addition of suitable protease inhibitors (EDTA, PMSF, leupeptin, etc.)*

Detergent Screening and Target Solubilization

- •Add solubilizing detergent to 20-100X the CMC. Use 1% DDM or alternative, as outlined in the text.
- •Incubate the membrane/detergent mixture at 4ºC for 4 hr to 12 hr. Shorter incubation times are possible, with the aid of further mechanical disruption.
- •Pellet any unsolubilized components by centrifugation at 100,000 x *g* for 1 hour.
- •*Suggested Solubilization Buffer: 300 mM NaCl, 1% DDM, imidazole (5 – 10 mM), 20 mM HEPES, pH 7.8, 10% glycerol, reducing agent, if appropriate. Resuspend the membrane pellet using 1-2 ml buffer per gram of original cell paste.*

Primary Purification by IMAC

- •Binding to IMAC resin at recommended flow rate for the resin type (*typically* ~ 1-5 ml/min).
- •Wash IMAC resin with an increasing concentration (up to 50 mM) to remove contaminating proteins
- • elute with >250 mM imidazole.
- •*(Optional: remove tag by protease digestion.)*
- •*Suggested IMAC Buffer: 300 mM NaCl, 0.05% DDM, 20 mM HEPES, pH 7.8, plus imidazole at the aforementioned concentrations and 10% glycerol, reducing agent, if appropriate*

Secondary Purification

- •**Size exclusion chromatography (SEC)**
- •Concentrate protein to ≥ 10 mg/ml , 1-2% of column volume, and load onto the size exclusion column (small columns, such as a Superdex S200 10/300 columns (GE Healthcare), are recommended).
- •Retain 'peak' protein fractions. The volume of pooled samples should be about 2-4X the volume of the injected sample. Broader peaks suggest protein heterogeneity or interaction with the column matrix.
- •*Suggested SEC Running Buffer: 200 mM NaCl, 0.02% DDM, 20 mM HEPES, pH 7.8, reducing agent, if appropriate.*
- •**Ion Exchange Chromatography (IEC)**
- •IEC can be performed as an alternative to SEC or if the target protein is insufficiently pure after the SEC step.

Concentrating Target Protein

- •Strategies and concerns for concentrating membrane proteins are outlined in the text.

Crystal Trials

Figure 3.2.3.1

Flow diagram of the membrane-protein purification strategy. Typically, only two chromatographic steps (affinity chromatography and SEC) are required for proteins that are expressed at reasonably high levels with a hexa-histidine tag. Ion-exchange chromatography (IEC) methods are sometimes employed, although they are not as common as SEC. If no crystals are obtained in initial sparse matrix screens, the protein can be exchanged to a different detergent and crystal trials attempted again (dotted arrow). Suggested 'first-try' buffers are indicated at each step.

3.2.3.2. Cell lysis and membrane isolation

Cellular lysis methods for the isolation of integral membrane proteins are similar to those for soluble targets. Cells over-expressing the protein of interest are re-suspended in a lysis buffer lacking detergent. Typically, high-flow/high-pressure cell-disruption devices are used, such as a continuous-flow homogenizer (EmulsiFlex, Avestin, Canada) or microfluidizer (Microfluidics Inc., Newton, Massachusetts, USA). Although these two devices achieve lysis by different mechanisms, both can disrupt the cells of almost all commonly used expression hosts, including yeast, and permit the rapid processing of large volumes. Other cell-disruption methods, such as sonication or nitrogen cavitation, can also be used for eukaryotic cells and, with slightly lower efficiency, *E. coli*. Protease inhibitors are included at this stage, although they are often not necessary in the later stages of purification. Following lysis, the membrane fraction of the cells is pelleted by ultracentrifugation.

3.2.3.3. Detergent extraction of membrane proteins

Following centrifugation, the crude-membrane pellet is re-suspended in a native lysis buffer. Detergent is then added to extract the membrane proteins from the lipid bilayer, at a molarity well above the critical micelle concentration (CMC, the concentration above which detergent molecules aggregate to form micelles). It is also more common than not that the same detergent used for solubilization is also used for subsequent purification and crystallization (Willis & Koth, 2008), albeit at a much lower concentration (typically just above the CMC). Broadly speaking, detergents fall into three main categories: charged (ionic), zwitterionic and non-charged (polar). Detergents containing no net charge are more likely to solubilize membrane proteins in their native state and are therefore more widely used for structural studies. In addition, detergents with sugar residues as head groups have proved particularly successful for the crystallization of membrane proteins, as have polyoxyethylene monoalkylethers (C_nE_m; Prive, 2007; Newstead *et al.*, 2008). Of all the membrane-protein structures solved to date, almost 70% have used one of just six different detergents for solubilization (Newstead *et al.*, 2008; Willis & Koth, 2008); with the exception of dodecyl-*N*,*N*-dimethylamine *N*-oxide (LDAO), all are non-charged. These six are, starting with the most prevalent, dodecyl-*β*-D-maltopyranoside (DDM), LDAO, octyl-polyoxyethylene (C8POE), decyl-*β*-D-maltoside (DM), octyl-*β*-D-glucoside (OG) and Triton X-100. Of these, DDM has been used for one out of almost every four crystallized targets and should be tested with any new membrane protein. The general properties of detergents and their use for membrane-protein solubilization have been reviewed by Hjelmeland (1990) and Neugebauer (1990).

The ability of detergents to solubilize target proteins can be tested on a small scale. The concentration of detergent that is optimal for solubilization should be determined empirically, although this can quickly become a multidimensional problem. A simple starting strategy, based on the purification methods for successfully crystallized membrane proteins, is to screen the aforementioned detergents at 1% (DDM, LDAO, Triton X-100) or 2% (C8POE, DM, OG). Detergents that are effective at these concentrations can be further screened to determine the optimal solubilization conditions (*i.e.* by varying detergent concentration *versus* solubilization time). Here, 'optimal' refers to the conditions yielding the highest level of soluble active target protein, or, if no activity assay exists, simply the conditions yielding the most target protein (but see caveats below). Although the level of solubilized target protein usually increases with time, many membrane proteins show reduced stability in detergent. It is advantageous, and more common, to minimize solubilization times (*i.e.* <4 h), thereby facilitating a more rapid purification. Physical methods such as sonication and passage through a cell disruptor may also be used to speed the solubilization process. Target proteins are considered soluble if, in the presence of detergent, they remain in solution after being subjected to 100 000 *g* for 1 h.

3.2.3.4. *General considerations for monitoring membrane-protein activity*

Although often overlooked (surprisingly so), developing a means of following membrane-protein activity can prove critical when optimizing solubilization and purification conditions. Unfortunately, there is no universal method for assaying the activity of all solubilized or purified membrane proteins. For receptors, obvious assays include those based on monitoring ligand binding. For many other targets, such as those critically dependent on the vectorial nature of the membrane for activity (*i.e.* ion channels), there may be no direct assay in the detergent-solubilized state. On the premise that *any* assay is better than none, some simple biophysical analyses are worth mentioning. Firstly, some membrane targets that function as multimers have been shown to retain quaternary structure in sodium dodecyl sulfate (SDS) and during polyacrylamide gel electrophoresis (PAGE) (Cortes & Perozo, 1997; Prive, 2007). This observation can provide a convenient means of monitoring quaternary structure under various solubilization or purification conditions. It has also been suggested that proteins demonstrating this behaviour may, in general, be stable in a variety of detergents, as is the case for the KcsA potassium channel (Cortes & Perozo, 1997). Secondly, for those multimeric targets whose quaternary structure is not maintained in SDS, monitoring the degree of cross-linking in various detergents/conditions can provide for a simple, albeit indirect, structural probe (Sukharev *et al.*, 1999). Thirdly, monitoring the sensitivity of a target protein to limiting amounts of protease can also provide a simple means of probing 'activity' or structure under various solubilization/purification conditions. For example, binding to magnesium alters the protease sensitivity of detergent-solubilized CorA channels, and this can be easily monitored by SDS–PAGE analysis of digested samples (Payandeh & Pai, 2006). In theory, such an assay could be used to probe structural changes upon ligand binding for almost any target, so long as a ligand is known. The growing use of Fab antibody fragments as aids to membrane-protein crystallization provides a fourth assay for some targets (Hunte & Michel, 2002; Day *et al.*, 2007). Antibodies (or antibody fragments) that bind a target protein in a cellular environment should also be able to bind that protein in detergent, as evaluated by an assay such as immunoprecipitation. Ideally, such antibodies are western-negative (*i.e.* they recognize nonlinear peptide epitopes that would only be present in a properly folded protein). Lastly, membrane proteins containing disulfide bonds (common in extracellular domains) often migrate more rapidly in SDS–PAGE than the same protein under reducing conditions. This can be used as an assay for proper protein folding in the cell, although this method does not provide information about target-protein stability in detergent.

3.2.3.5. *Primary purification: affinity chromatography*

Given that most membrane proteins are cloned with a histidine tag, the most common method for their primary purification is immobilized metal affinity chromatography (IMAC), used in >80% of recombinant membrane-protein structures (Willis & Koth, 2008; Newby *et al.*, 2009). IMAC methods for membrane proteins do not differ significantly from those commonly used for soluble proteins, with the notable exception that detergent is required in all buffers. During the wash and elution steps, the detergent concentration is typically reduced to a level above the CMC that is only just sufficient to maintain target-protein solubility. Ideally, the ratio of micelles to membrane-protein molecules is $\sim$2 at this and subsequent purification stages [for an in-depth analysis, the reader is strongly encouraged to read Helenius *et al.* (1979) and Wiener (2004)]. The histidine tag may be removed after IMAC elution, although it is also worthwhile to proceed with a sample that retains the tag, since they provide critical lattice contacts in some protein crystals (Carson *et al.*, 2007).

3.2.3.6. *Secondary purification: size-exclusion and ion-exchange chromatography*

For most successful structures, target membrane proteins are sufficiently pure for crystal trials after a two-step purification: IMAC followed by size-exclusion chromatography (SEC) or ion-exchange chromatography (IEC) (Willis & Koth, 2008; Newby *et al.*, 2009). A detailed strategy is outlined in Fig. 3.2.3.1. SEC is the most common secondary (*i.e.* post-IMAC) method, represented in about half of all successful membrane-protein structures (Willis & Koth, 2008). IEC methods have been used less frequently, being employed for about one out of every four structures (Willis & Koth, 2008). The simple fact that some integral membrane proteins lack sufficient polar area to interact effectively with ion-exchange resins may account for the difference. Both methods permit the exchange of one detergent (*i.e.* that used for solubilization) for another or to a higher grade (a consideration, given the high cost of many detergents). Ion-exchange methods are likely to give a more complete detergent exchange, although this does not necessarily improve crystallization outcomes (Lemieux *et al.*, 2003). In fact, incomplete detergent exchange and/or incomplete removal of specifically bound lipids can prove beneficial in downstream crystal trials (Long *et al.*, 2007).

3.2.3.7. *Concentrating membrane-protein samples for crystallography*

Concentration of the target membrane protein is typically required prior to crystallization. Many different concentration methods can be used (*i.e.* those employed for soluble proteins), although some caution is warranted. Detergent will normally concentrate with the protein, since most detergent micelles are too large to pass through typical dialysis or concentration membranes. This can be detrimental to crystallization; high detergent concentrations can denature protein or limit diffraction (Wiener, 2004). As a general rule, the highest-molecular-weight cutoff membrane that does not permit passage of the target protein should be used, as this will allow the passage of at least some protein-free detergent micelles. Also, any size-exclusion steps should be performed at a relatively high protein concentration (10–20 mg ml^{-1} or higher) to minimize volumes. Purified protein may also be dialysed to exchange non-detergent buffer components, so long as the detergent concentration of the bulk solution is maintained just above the CMC. However, the dialysis of many detergents will proceed slowly (days to weeks). Accordingly, dialysis does not appear to be a widely used method for controlling detergent concentration prior to crystallization (reviewed by Willis & Koth, 2008).

3.2.4. Common purification pitfalls and prioritized alternative strategies

3.2.4.1. Poor solubility of the target protein

If the target protein does not remain soluble during purification, an obvious alternative strategy is to test different detergents or detergent combinations. Given that just a handful of different detergents have been used to solubilize and crystallize most membrane proteins, testing alternatives is usually not a daunting task. The most common method of detergent exchange is SEC (Fig. 3.2.3.1).

The zwitterionic lyso-lipid mimetic detergents such as FOS-CHOLINE 12 (dodecylphosphatidylcholine) or 14 (FC12 and FC14; Anatrace, Maumee, Ohio, USA) will solubilize many membrane proteins (Eshaghi *et al.*, 2005) and there are a few reports of their use in crystallography [MscS mechanosensitive channel (Bass *et al.*, 2002); protein-conducting channel (van den Berg *et al.*, 2004)]. Should solubilization screening with the more commonly used detergents prove ineffective, it may be possible to solubilize first with a 'stronger' more lipid-like detergent, such as FC12, and then exchange to a non-charged detergent, such as DDM, during purification.

3.2.4.2. The isolated target protein does not crystallize

Although an in-depth analysis of membrane-protein crystallization methods is beyond the scope of this chapter (see instead Chapter 4.2), there are many purification parameters that can be varied to improve crystallization outcomes should initial trials fail to yield 'hits' or well diffracting crystals. Perhaps the foremost method is to exchange the protein into an alternative detergent or detergent mixture, typically by SEC, and repeat the crystal trials. Since the vast majority of membrane-protein structures have used one of only a handful of detergents (see above), it is likely that sampling even just a small number of other detergents would dramatically increase the likelihood of obtaining or optimizing crystals. Also, an increase in the alkyl-chain length by one methylene group (*i.e.* nonyl- *versus* octyl-β-D-glucoside) often leads to an increase in protein stability, and this too can improve crystallization outcomes (Wiener, 2004). If significant covalent disulfide aggregation of the protein is observed during purification, alkylation of free cysteines should be considered during the early stages of target-protein isolation. Other parameters that could be varied include the solution pH, salt concentration and temperature, or supplementing with known ligands, to name just a few.

3.2.5. Summary

There are many possible routes for the expression and isolation of membrane proteins for structural studies, and many factors can affect the likelihood of obtaining diffraction-quality crystals. The daunting prospect for almost any new membrane target is that every stage, including expression, solubilization, purification and crystallization, will prove challenging. In this light, it is encouraging that remarkably similar techniques have been employed for many successfully crystallized membrane targets, including, for example, the observation that most structures have been solved using just a handful of different detergents throughout the isolation and crystallization steps. It is equally significant that simple two-step purification strategies predominate. Clearly, new methods for the production of membrane proteins will continue to be developed. Nevertheless, for a field that is quite likely to be entering an acute phase of growth, a solid foundation has been established for reasonable 'first-try' strategies.

PART 4. CRYSTALLIZATION

Chapter 4.1. General methods

C. Sauter, B. Lorber, A. McPherson and R. Giegé

4.1.1. Introduction

4.1.1.1. Prologue

Macromolecular crystals are much softer than salt crystals. They contain ∼50% of solvent on average, with values ranging from as little as 25 up to 90%. A direct consequence is that, although morphologically indistinguishable, crystals of macromolecules differ in many respects from crystals of low-molecular-mass compounds. While the latter exhibit firm lattice forces, are highly ordered, generally physically hard and brittle, easy to manipulate, can usually be exposed to air, have strong optical properties and diffract X-rays intensely, crystals of macromolecules are, by comparison, smaller in size, they crush easily, disintegrate if allowed to dehydrate, exhibit weak optical properties and diffract X-rays poorly. They are temperature sensitive and undergo extensive damage after prolonged exposure to radiation.

Proteins or nucleic acids build up a crystalline scaffold, which may be imagined as an ordered gel with extensive interstitial spaces through which small molecules can diffuse freely. In proportion to molecular mass, large macromolecules establish far fewer packing interactions than do small molecules inside crystalline lattices. Since these contacts are responsible for the integrity of the crystals, this largely explains the differences in properties between the two types of crystals. Thus, liquid channels and solvent cavities are directly responsible for the generally poor diffraction properties of macromolecular crystals. Owing to the large spaces between adjacent molecules and the related weak lattice forces, every molecule in the crystal may not occupy exactly equivalent orientations and positions. Furthermore, because of their structural complexity and their conformational dynamics, macromolecules in a given crystal form may exhibit slight variations in their folding patterns or dispositions of side chains.

However, high solvent content is not as negative as it might appear at first glance. It allows maintenance of the macromolecular structures virtually unchanged from those in bulk solvent. As a consequence, ligand binding, enzymatic and spectroscopic characteristics, and other biochemical features are essentially the same as for the native molecule in solution. In addition, the dimensions of solvent channels are such that conventional chemical compounds, such as ions and heavy atoms, substrates or other ligands, may be freely diffused into and out of the crystals. Thus, many crystalline enzymes, though immobilized, are completely accessible for experimentation through alteration of the surrounding mother liquor.

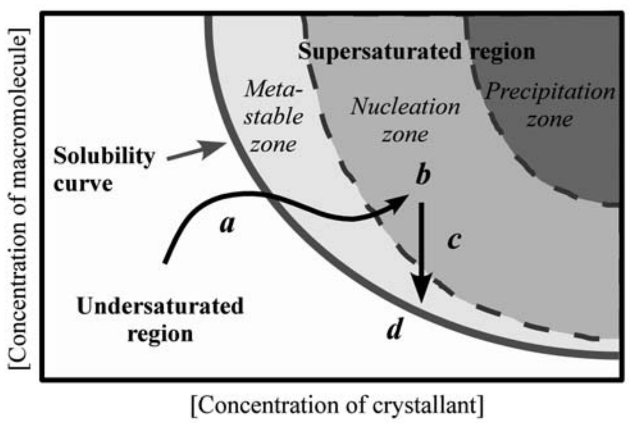
The intrinsic instability of most macromolecules requires that conditions suitable for crystal growth are those that do not perturb their molecular properties. This explains why crystals must be grown from solutions compatible with the target macromolecules, *i.e.* within a narrow range of pH, temperature or ionic strength. Finally, because hydration is essential for the maintenance of structure, crystals of macromolecules must be always bathed in the mother liquor, even during data collection (except in the practice of cryocrystallography).

4.1.1.2. Crystallization principles

The crystallization of biological macromolecules has often been considered unpredictable, although it obeys the same principles as that of small molecules (Giegé *et al.*, 1995; McPherson *et al.*, 1995; Rosenberger, 1996; Chernov, 2003; McPherson & Giegé, 2007). It is, similarly, a multiparametric process. The difference compared with conventional crystal growth arises from the biochemical and biophysical properties of proteins or nucleic acids, and crystallization methods must take into account these features. The methods described below apply for most proteins, large RNAs, multimacromolecular complexes and viruses (for small oligonucleotides or peptides, crystallization by dialysis is not appropriate). For hydrophobic membrane proteins, special techniques are required (see Chapter 4.2).

Crystallization proceeds from macromolecules in solution that ‘aggregate’ upon entering a supersaturated state and eventually undergo a phase transition. This leads to nuclei formation and ultimately to crystals that grow by different mechanisms. Supersaturation is the driving force of crystallization and is defined as the ratio $[C]/[S]$, where $[C]$ and $[S]$ are the initial concentration of the macromolecule and its final concentration at saturation, *i.e.* its solubility. Nucleation is homogeneous when nuclei form in the bulk of the solution, but heterogeneous when they preferentially form on walls of crystallization vessels, on solid particles (dust, aggregates, seeds), or on the surface of existing crystals. Unlike most conventional crystals, protein crystals are, in general, not initiated from seeds, but are nucleated *ab initio* at high levels of supersaturation that can reach 200 to 1000% (in what follows and for simplicity, the generic name ‘protein’ is used for macromolecule). It is this high degree of supersaturation that, in large part, distinguishes protein crystal formation from that of conventional crystals. That is, once a stable nucleus has formed, it subsequently grows under very unfavourable conditions of excessive supersaturation. Distant from the metastable zone, where ordered growth could occur, crystals rapidly accumulate nutrient molecules, as well as impurities. They also concomitantly accumulate statistical disorder and a high frequency of defects that exceeds those observed for most conventional crystals.

The different stages of crystallization (*i.e.* pre-nucleation, nucleation, growth, cessation of growth) can be visualized in a phase diagram (Fig. 4.1.1.1). In short, phase diagrams are divided into undersaturated regions (where proteins are soluble) and supersaturated regions (where protein crystals nucleate and grow) delimited by the solubility curve. The supersaturated region is thermodynamically out of equilibrium and can be divided into three kinetically dependent domains: a precipitation domain (at extreme supersaturation) where macromolecules rapidly separate from solution in a solid state either amorphous or microcrystalline, a domain (at lower supersaturation) where



Biochemical parameters
Purity of the macromolecule
Ligands, inhibitors, effectors
Aggregation state of the macromolecule
Post-translational modifications
Source of macromolecule
Proteolysis or hydrolysis
Chemical modifications
Genetic variants
Inherent symmetry of the macromolecule
Stability of the macromolecule
Isoelectric point
History of the sample

Chemical parameters
pH
Crystallant type
Crystallant concentration
Ionic strength
Specific ion effects
Supersaturation
Reductive or oxidative environment
Concentration of the macromolecule
Metal ions
Crosslinkers or polyions
Detergents, surfactants or amphophiles
Non-macromolecular impurities

Physical parameters
Temperature variation
Contact surfaces
Methodology or approach to equilibrium
Gravity
Pressure
Time
Vibrations, sound or mechanical perturbations
Electrostatic or magnetic fields
Dielectric properties of the medium
Viscosity of the medium
Rate of equilibration
Homogeneous or heterogeneous nucleants

Figure 4.1.1.1

Crystallization is a multiparametric process under the control of a great variety of biochemical, chemical and physical parameters. The crystal grower can play with them to drive a macromolecule from the soluble towards the crystalline state. In the top left, a typical two-dimensional phase diagram illustrates how this can be achieved. (*a*) By modifying two parameters (concentrations of macromolecule and crystallant), the system will move from the undersaturated region where the macromolecule is soluble into the supersaturated region beyond the solubility curve where it will try to escape from the solution. The prenucleation trajectory essentially depends on the crystallization method (see Fig. 4.1.3.1). (*b*) As soon as they enter the supersaturation region, macromolecules will tend to aggregate. However, the system needs to cross an energy barrier to produce stable molecular assemblies, the nuclei, and this only happens in the so-called nucleation zone. (*c*) When stable nuclei are formed, they will capture more macromolecular entities from the mother liquor and produce three-dimensional crystals. (*d*) Crystals will grow until the system comes back to the solubility curve, crossing the metastable zone. Growth stops and crystals are in dynamic equilibrium with the mother liquor. When the system is driven to high supersaturation, macromolecules may rather produce amorphous or microcrystalline precipitates than useful monocrystals. Note that the limits between zones of the supersaturated zone (dashed curve) move with time.

nucleation occurs spontaneously and a metastable domain (at low supersaturation) where nucleation does not occur spontaneously but where crystals grow. This domain is favourable for seeding. The wisdom of the crystal grower will be to take advantage of an overall understanding of phase diagrams for designing crystallization strategies and selecting favourable solvent conditions (Sauter, Lorber *et al.*, 1999; Asherie, 2004).

4.1.2. Main parameters that affect crystallization of macromolecules

4.1.2.1. Crystallizing agents

Crystallizing agents (also referred to as crystallants or precipitants) are defined as those chemical species that are able to precipitate a soluble macromolecule and hence to bring it into a supersaturated state needed for its crystallization. They fall into four categories: (i) salts, (ii) organic solvents, (iii) long-chain polymers, and (iv) low-molecular-mass polymers and non-volatile organic compounds (McPherson, 1990). The first two classes are typified by ammonium sulfate and ethanol; higher polymers such as PEGs (polyethylene glycols) of molecular weight (M_r) > 1000, are characteristic of the third. In the fourth are placed compounds such as MPD (2-methyl-2,4-pentanediol) and low-molecular-mass PEGs.

Salts. Salts exert their effects by dehydrating proteins through competition for water molecules (Green & Hughes, 1955). Their ability to do this is roughly proportional to the square of the valences of the ionic species composing the salt. Thus, multivalent ions, particularly anions, are the most efficient. One might think there would be little variation between different salts, so long as their ionic valences were the same, or between two different sulfates, such as lithium and ammonium sulfates. This, however, is often not the case. In addition to salting out, which is a dehydration effect, or lowering of the chemical activity of water, there are specific protein–ion interactions that have other consequences (Riès-Kautt & Ducruix, 1991; Ducruix & Giegé, 1999). This is true because of the polyvalent character of individual proteins, their structural complexity, and the dependence of their physical properties on environmental conditions and interacting molecules. Therefore, restricting the search to one or two salts is never sufficient when attempting to crystallize a protein. Changing the salt may produce crystals of varied quality, morphology and diffraction properties.

It is usually not possible to predict the molarity of a salt required to crystallize a particular protein without some prior knowledge of its behaviour. In general, the concentration is just a small percentage less than that yielding an amorphous precipitate. To determine the precipitation point with a given crystallant, a 10 µl droplet of a 5–15 mg ml^{-1} protein solution is placed in the well of a depression slide and observed under a microscope as increasing amounts of salt solution or organic solvent (in 1–2 µl increments) are added. If the well is sealed between additions with a coverslip, the increases can be made over a period of many hours. Indeed, the droplet should equilibrate 10–30 min after each addition, and longer in the neighbourhood of the precipitation point.

Widely used and the most successful salt to grow protein crystals is ammonium sulfate. A variety of other salts included in crystallization screens yield success as well. Sodium malonate, not systematically present in screens, deserves particular attention, since it gave the highest success rate (better than ammonium sulfate) in a comparative study designed to identify the most effective salts for protein crystallization (McPherson, 2001). Following this example, other organic salts have been added to the repertoire (McPherson & Cudney, 2006).

Organic solvents. The most common organic solvents (volatile compounds) utilized are ethanol, methanol, isopropanol, acetone and dioxane. They have been frequently used for crystallizing nucleic acids, particularly tRNAs and duplex oligonucleotides

(Dock *et al.*, 1984). This, in part, stems from the greater tolerance of polynucleotides to organic solvents and their polyanionic character, which appears more sensitive to dielectric effects than proteins. Volatile organic solvents should be used at low temperature and should be added slowly and with good mixing.

Long-chain polymers. PEGs are polymers of various lengths that are useful in crystallogenesis (McPherson, 1976). The larger species with $M_r > 1000$ exist at room temperature as either waxy solids or powders. The M_r's specified by manufacturers are mean values, and the distribution around these means varies. In addition to volume exclusion properties, PEGs share characteristics with salts that compete for water and produce dehydration, and with organic solvents that reduce the dielectric properties of the medium. PEGs also have the advantage of being effective at minimal ionic strength and providing low-electron-density media. The first feature is important because it leads to stronger affinities for ligands than high-ionic-strength media. Thus, there is greater ease in obtaining heavy-atom derivatives and in forming protein–ligand complexes. The second characteristic, their low electron density, implies a lower noise level for structures derived by X-ray diffraction.

The most useful PEGs in crystallogenesis are those in the range 2000–8000. Sizes are generally not completely interchangeable for a given protein, and this parameter has to be optimized by empirical means. An advantage of PEG over other crystallants is that most proteins crystallize within a rather narrow range of PEG concentrations (~4–18%). In addition, the PEG concentration at which crystals form is rather insensitive, and if one is within 2–3% of the optimal value, some success will be achieved. The advantage is that, when conducting initial trials, one can use a fairly coarse selection of concentrations. This means fewer trials with a corresponding reduction in the amount of material expended. Note that PEGs are often used in conjunction with salts.

Since PEG is not volatile, this agent must be used like salt and equilibrated with the protein by dialysis, slow mixing or vapour diffusion. This latter approach is the most popular. When the reservoir concentration is in the range 5–12%, the protein solution to be equilibrated should initially be at about half that concentration. When the target PEG concentration is higher than 12%, it is advisable to initiate the equilibration at no more than 4–5% below the final value. This reduces lags in time during which the protein might denature. Crystallization of proteins with PEG has proved most successful when ionic strength is low, and more difficult when high. If crystallization proceeds too rapidly, addition of some neutral salt may be used to slow growth. PEG can be used over the entire pH range and a broad temperature range. It should be noted that solutions with PEG may serve as media for microbes, particularly moulds, and if crystallization is attempted at room temperature or over extended periods of time, then retardants, such as azide (~0.1%), must be included in the protein solutions.

Low-molecular-mass polymers and non-volatile organic compounds. Low-molecular-mass PEG species with $M_r < 1000$, MPD and glycerol are widely used. These are oily liquids that increase the viscosity of the crystallization samples. Glycerol and other polyols have structure-ordering potential and might be useful for crystallizing flexible proteins (Sousa, 1995). MPD has properties midway between PEG and organic solvents, which makes it one of the most successful crystallants for promoting crystallization of biological macromolecules (Anand *et al.*, 2002). Besides efficacy with proteins, ~50% of oligonucleotides were crystallized with MPD (Li *et al.*, 2007). These low-molecular-mass compounds are often used in combination with salts or long-chain PEGs.

Recent data show that room-temperature ionic liquids have the potential for macromolecular crystallogenesis (Pusey *et al.*, 2007) and can be added to the list of crystallants. They are organic salts that can solubilize proteins while preserving structural stability and enzymatic activity. With regard to crystallization applications, it is worth noticing that imidazolium-based ionic liquids enhance protein folding and suppress aggregation (Lange *et al.*, 2005). As a promising result, several ionic liquids used in the range 3–30%(v/v) yielded crystals of trypsin and lysozyme (Judge *et al.*, 2009).

4.1.2.2. Physical, physical–chemical and biochemical variables

Many physical, chemical and biological variables influence, to a greater or lesser extent, the crystallization of macromolecules (Fig. 4.1.1.1). The difficulty in assigning the relative importance for each factor is substantial for several reasons. First, each macromolecule has different surface properties and this even applies to molecules that differ by no more than one or a few residues. Therefore one can hardly predict in advance the specific values of a variable or sets of conditions that might be most profitably explored. Furthermore, crystallization parameters are not independent and their interrelations may be difficult to discern. Thus, it is not easy to elaborate firm guidelines related to physical or chemical factors that can increase the success in crystallizing a particular macromolecule. Among them, only temperature and pH have been studied carefully. For pressure or magnetic and electric fields, few investigations have been carried out and virtually nothing is known on the effects of sound, vibrations or viscosity on the growth or final quality of protein crystals (see Section 4.1.4.2).

Current physical–chemical variables. Temperature may be of great importance (Judge *et al.*, 1999; Astier & Veesler, 2008; Lin *et al.*, 2008). In general, it is wise to conduct parallel investigations at 4 and 20 °C. Even if no crystals are observed at either temperature, differences in the solubility behaviour of a protein with various crystallants and effector molecules may give some indication as to whether temperature is likely to play an important role (Christopher *et al.*, 1998). Generally, the solubility of a protein is more sensitive to temperature at low ionic strength than high. One must remember, however, that diffusion rates are less, and equilibration occurs more slowly at colder than higher temperature, so that the time required for crystal formation may be longer at colder temperatures. Although most crystallization trials are done at low (~4° C) or medium (~20 °C) temperatures, warmer temperatures in the range 35–40 °C should not be ignored, particularly with molecules that tend to aggregate and with nucleic acids (Dock-Bregeon *et al.*, 1988).

Another important variable is pH (Judge *et al.*, 2009). This follows since the charge character of a macromolecule and all of its consequences are intimately dependent on the ionization state of its components. Not only does its net charge change with pH (and the charge distribution), but also its dipole moment, conformation and often its aggregation state. Thus, an investigation of the behaviour of a specific macromolecule as a function of pH is an essential analysis that should be carried out in performing crystallization assays. Various buffer systems that are compatible with macromolecules are available for that purpose (Newman, 2004). As with temperature, the procedure is, first, to conduct trials at coarse intervals over a broad pH range and then to refine trials in the neighbourhood of those that showed promise. In refining the pH for optimal growth, it should be recalled that the difference between amorphous precipitate, microcrystals and large single crystals might be due to a ΔpH of less than half a unit.

Other physical variables. Convection and diffusion are two correlated parameters that govern mass transport during the crystallization process, and studies on the physics of macromolecular crystal growth, in particular in relation to microgravity research (Giegé *et al.*, 1995; McPherson, 1996; Kundrot *et al.*, 2001; Helliwell & Chayen, 2007), have evaluated their importance and led to advanced methods of crystallization (see Section 4.1.4). On the other hand, mechanical or other types of physical perturbation of the crystallization media, *e.g.* by external electric or ultrasonic fields (Nanev & Penkova, 2001; Kakinouchi *et al.*, 2006), by continuous light irradiation (Veesler *et al.*, 2006) and by laser pulses (Lee *et al.*, 2008), might be used to induce nucleation. Local increase of protein concentration due to laser-induced cavitation could be a trigger of nucleation (Yoshikawa *et al.*, 2009).

Biochemical variables. It is now generally appreciated that, indeed, the protein is itself the most important and influential parameter in the crystallization endeavour (Dale *et al.*, 2003). When conventional approaches to crystallization have been exhausted there are two remaining options: further purifying the protein, or modifying the protein. The latter may be accomplished by genetic means using recombinant DNA techniques; that is, single or multiple point mutations may be introduced, or truncated forms of the polypeptide generated (see Section 4.1.2.4). Alternatively, traditional chemical reactions may be used to modify existing amino acids, or exposure to modifying enzymes may be employed, for example, the production of truncations by limited proteolysis. There are many examples of truncated proteins being successfully crystallized when the full-length polypeptide could not, *e.g.*, with many aminoacyl-tRNA synthetases (Giegé *et al.*, 2008). With the predictive capability of modern amino-acid sequence analysis and mass spectrometry to identify domains within proteins, designed constructs of predetermined lengths are becoming increasingly used. It has also been suggested that some surface amino acids, such as lysine and glutamic acid, inflict entropic costs when a protein crystallizes (Derewenda, 2004). Modification of such residues by reductive methylation appears to be a useful approach (Kim *et al.*, 2008) that in some cases enhances crystallizability. For instance, the addition of two methyl groups on the side chain of nine lysine residues of a nuclease introduced 44 cohesive CH intramolecular contacts and resulted in crystals diffracting at 1.2 Å resolution (Shaw *et al.*, 2007).

Histidine tags and proteins conjugated with a second protein, such as the maltose binding protein, are frequently produced as a basis for purification procedures for recombinant proteins. There is no reason why these ‘tagged’ or conjugated proteins should not crystallize and, indeed, many of them do. On the other hand, removal of the tag or conjugate and subsequent crystallization trials provide a further opportunity to obtain crystals of a protein, and should certainly be tried (Carson *et al.*, 2007).

Another possibility to gain access to the structure of proteins recalcitrant to crystallize is to try crystallization of their orthologues. Indeed, proteins are adapted to their cellular environments and orthologues of the same physiological function can exhibit structural and physical–chemical idiosyncrasies leading to modified crystallizability. Thus proteins and macromolecular assemblages from extremophile organisms often crystallize more readily than their cousins from mesophiles or from higher eukaryotes, as shown for instance with aminoacyl-tRNA synthetases (Giegé *et al.*, 2008).

In nucleic acid crystallization, the large size of natural DNA and of many RNA molecules necessitates the design and preparation of adequate structural modules or domains amenable to crystal production. Tailoring an adequate module is often the prerequisite for its crystallization (Ducruix & Giegé, 1999; Holbrook *et al.*, 2001; Golden & Kundrot, 2003). Since RNA architecture is very modular, specific protein-binding domains can be introduced (typically small RNA hairpins) in the target RNA sequence to promote the association with a protein partner (*e.g.* the spliceosomal protein U1A) and hence to increase the possibilities of making packing interactions (Ferré-D’Amaré, 2010). Similarly, this engineering approach can be applied to proteins. A typical example is the production of crystals diffracting to high resolution of a G-protein-coupled receptor. In that case one flexible loop of this membrane protein was replaced by the sequence of T4 lysozyme and this globular exogenic domain created new contacts leading to three-dimensional packing (Cherezov *et al.*, 2007). Another example of engineering is the introduction of a leucine half-zipper into an aminoacyl-tRNA synthetase that has engendered multiple high-quality crystals (Guo *et al.*, 2010).

4.1.2.3. *Additives*

Certain chemical compounds or small molecules may have dramatic effects on the success of protein crystallization. Additives, as they are often called (McPherson, 1982, 1999; Sauter, Ng *et al.*, 1999), can be decisive in macromolecular crystallization. The most commonly used type of additives, and the only class for which we have any rational basis, are those which may, for physiological reasons, be bound by the protein with consequent favourable changes in its physical–chemical properties or conformation. These include coenzymes and prosthetic groups, inhibitors, enzymatic products, ions and other effector molecules. Often the liganded form is structurally defined and stable, while the unliganded form is not, which will lead to the crystallization of the former and not of the latter. Polyamines and metal ions are useful for nucleic acids (Dock *et al.*, 1984; Ducruix & Giegé, 1999). In terms of crystallization, complexes have to be treated as almost entirely separate problems. This may permit a new opportunity for growing crystals if the native molecule is obstinate. Just as natural substrates or inhibitors are often useful, they can also have the opposite effect of obstructing crystal formation. In such cases, care must be taken to eliminate them from the mother liquor and from the purified protein before crystallization is attempted.

Numerous cases have, however, been reported where molecules were observed to make crucial interactions between macromolecules in the crystal that either helped guide or secure formation of the lattice. Such molecules sometimes had a physiological basis for their unexpected presence, but frequently not. They simply provided essential or at least helpful cross-links within the crystal. Additives that are used in protein crystallization or that might be appropriate for use in crystallization may be classified into nine categories.

Small physiological ligands. Physiologically or biochemically relevant small molecules such as coenzymes, substrate analogues, inhibitors, metal ions, prosthetic groups *etc.* are the first. These bind at the active sites of enzymes, or at specific sites elsewhere on protein molecules, and may promote more stable, homogeneous conformations, or they may induce conformational changes into alternate states. In any case, the ultimate protein–ligand complex may exhibit a more monodisperse, less dynamic character. The pertinent molecules are, here, specific to the individual protein under study, and their selection for inclusion in mother liquors is amenable to rational analysis informed by the enzymology and biochemistry of the protein under study. That is, one considers all of the possible ligands of the protein and includes them in the screen of potential crystallization conditions.

Chemical protectants. These include reductants, such as 2-mercaptoethanol, gluthathione or dithiothreitol, which prevent oxidation, heavy metal ions, scavengers such as EDTA and EGTA (ethylenediaminetetraacetic acid and ethylene glycol tetraacetic acid), and compounds intended to prevent microbial infection such as sodium azide, pheno- or chlorobutanol. These compounds are generally included for well understood reasons, their effects are predictable and their impact on the crystallization process usually, but not always, of marginal significance. They prevent protein 'ageing', as do protease or nuclease inhibitors (Ducruix & Giegé, 1999), and are desirable when crystallization requires a long period of time to reach completion or when carried out at room temperature in PEG, or in low-ionic-strength solutions (*i.e.* conditions favourable for the growth of contaminating microorganisms).

Solubilizing agents and detergents. These include quaternary ammonium salts (Mirzabekov *et al.*, 1972), sulfobetains (Goldberg *et al.*, 1996), chaotropes like urea (Bolen, 2004), and a range of surfactant and detergent molecules (Neugebauer, 1990; Zulauf, 1990; Wiener, 2004). Because of the interest in membrane proteins, this class of additives was extensively studied and has been broadly applied to many proteins. Remarkably, there is still no consensus on which are most useful, which should be included in screening conditions, or even how they function in the solubilization of macromolecules. Note that ionic liquids at low concentration can enhance protein solubility and were shown to improve crystallization (Chen *et al.*, 2010).

Poisons. Poisons, as they have traditionally been called (McPherson, 1982, 1999), were originally employed to reduce twinning. These are generally low concentrations, 1–5%(*w*/*v*), of common organic solvents. They include compounds such as ethanol, dimethyl sulfoxide, acetone, dioxane, butanol or MPD. Their role in the crystallization process, even after 50 years of use, remains obscure. They probably enhance the solubility of the proteins and slightly reduce the degree of supersaturation in the mother liquor, as well as lower the dielectric constant of the medium, but they may have other effects as well.

Osmolytes, co-solvents and cosmotropes. These are compounds that exert their effects at relatively high concentrations, 1 *M* or more, and include a wide range of molecules such as sucrose, trehalose and other sugars, proline, trimethyl amine *N*-oxide, glycine, betaine, taurine, sarcosine, and a host of others (Washabaugh & Collins, 1986; Jeruzalmi & Steitz, 1997; Bolen, 2004; Collins, 2004). The effect of their inclusion in the mother liquor is usually to stabilize the native conformation of the protein by altering the interaction of the protein's surface with water, or by altering the hydration layer and possibly the structured waters.

Reversible cross-linkers. It has been proposed that the conformations of proteins might be stabilized, and their dynamic character reduced, by providing the proteins with small molecules that could reversibly cross-link charged groups (carboxyl and amino groups) on the protein's surface, or form intramolecular hydrogen-bonding networks using surface polar groups (Maclean *et al.*, 2002). The molecules that have been explored are usually multivalent molecules such as diamino- or dicarboxylic acid-containing molecules, or aliphatic moieties of various lengths carrying some combination of charged groups. It is not known whether the stabilization of proteins by this means is significant enough to affect their crystallization or not. This potential mechanism of altering crystallization behaviour, however, may indeed be pertinent.

Compounds favouring lattice interactions. Classes of compounds useful for stabilizing proteins through non-covalent intramolecular bonds, as described above, may also help create and stabilize protein crystals by interposing themselves between protein molecules and forming intermolecular cross-links (McPherson, 1999; McPherson & Cudney, 2006; Larson *et al.*, 2007, 2008). These cross-bridges may involve purely electrostatic interactions, or they may rely on hydrogen-bonding arrangements as well. The compounds most favourable for forming such 'lattice interactions' are, again, likely to be multivalent charged compounds, but one might expect that their length, or 'reach', would need to be greater, since they would have to extend from one protein molecule to another.

Nucleation and solubility enhancers. A special class of additives would be those materials or compounds that somehow serve to enhance nucleation, including unique surfaces. These may include low concentrations of PEG (Ray & Bracker, 1986), or other polymeric substances such as jeffamine emulsified in solutions of high salt concentration (Kuznetsov *et al.*, 2000, 2001). The microdroplets of the polymeric phase serve to concentrate the protein locally and provide an interface for nucleation to occur. This category should probably also include things like the gel used in cubic lipidic phase crystallization (Nollert, 2004; Caffrey & Cherezov, 2009) and surfaces that promote epitaxy and heterogeneous nucleation (McPherson & Shlichta, 1988*b*; Chayen *et al.*, 2006; Thakur *et al.*, 2008; Saridakis & Chayen, 2009).

Nucleation enhancers when mixed with current crystallants can also enhance protein solubility (at solute/crystal equilibrium). This is the case, *e.g.*, for acetonitrile, dimethyl sulfoxide, glycerol, MPD and PEGs at relatively high concentrations. As shown with lysozyme and xylose isomerase crystallized, respectively, in the presence of glycerol and acetonitrile, the beneficial effects are nucleation at lower supersaturation and crystals of lower mosaicity (Gosavi *et al.*, 2009).

Ionic liquids. These crystallants (see Section 4.1.2.1) can also be considered as additives. Used in the concentration range 0.05–0.15 *M*, several of them (*e.g.* 1-ethyl-3-methylimidazolium tetrafluoroborate) improved the crystallizability of lysozyme, trypsin and an Fab complex, probably by subtle changes in solution conditions since no ionic liquid ions were observed in the crystal structures (Judge *et al.*, 2009; Chen *et al.*, 2010).

4.1.2.4. *Purity and homogeneity*

The concept of purity is of utmost importance in macromolecular crystallogenesis (Giegé *et al.*, 1986; Rosenberger *et al.*, 1996), even though some macromolecules may crystallize readily from impure solutions (Judge *et al.*, 1998). In practice, macromolecular samples should be cleared of undesired macromolecules and small molecules and, in addition, should be pure in terms of sequence integrity and conformation.

Contaminants can have deleterious effects when they interact with the macromolecule or compete for sites on growing crystals and consequently generate growth disorders (Vekilov & Rosenberger, 1996). Thus, part-per-million amounts of foreign molecules can induce the formation of non-specific aggregates, alter macromolecular solubility, or interfere with nucleation and crystal growth (McPherson *et al.*, 1996, 2004; Moreno *et al.*, 2005; Thomas *et al.*, 1998). These effects are reduced in gel media (Hirschler *et al.*, 1995; Provost & Robert, 1995).

On the other hand, macromolecules that are apparently pure may be microheterogeneous in sequence and/or conformation. Their causes are multiple and can be revealed by analytical tools, such as polyacrylamide gel electrophoresis, isoelectric focusing, nuclear magnetic resonance and mass spectroscopy, but are often overlooked. The most common causes are partial hydrolysis and post-synthetic modifications. Proteolysis represents a major difficulty that must be overcome during protein isolation. In RNAs, hydrolytic cleavages induced by nucleases, metal ions or alkaline pH are common causes of microheterogeneity. These processes can be inhibited by addition of protease or nuclease inhibitors and metal chelators during purification (Ducruix & Giegé, 1999). Heterogeneity in post-synthetic modification patterns in proteins or RNAs can be the result of functional necessity but can also occur when cloned macromolecules are overproduced. Conformational heterogeneity may also originate from ligand binding, intrinsic flexibility of the macromolecule backbones, oxidation of cysteine residues or partial denaturation. Structural homogeneity may be improved by truncation of the flexible parts of the macromolecule under study (see Section 4.1.3). This can also be done *in situ* by addition of trace amounts of protease to crystallization assays (Wernimont & Edwards, 2009). The many reasons that can account for such subtle degradations or modifications explain why altered versions of a macromolecule can be the worst contaminants for its crystallization. Accordingly, the macromolecule itself must be considered as an essential parameter in crystallization (Dale *et al.*, 2003). Control of these phenomena is of crucial importance for the crystallization of macromolecular assemblages, such as the ribosome (Auerbach-Nevo *et al.*, 2005).

Many crystal growers have found a correlation between the outcome of crystallization assays (*i.e.* number of crystals, crystal habit, volume and best diffraction properties) and the quality of macromolecular samples. For this reason, one should never spoil a 'pure' batch by mixing it with another 'pure' one, that may differ as far as microheterogeneities or minute contaminants are concerned. Altogether, purity, good solubility, structural homogeneity and absence of aggregates are good criteria for protein crystallizability (D'Arcy, 1994; Ferré-D'Amaré & Burley, 1997). Dynamic light scattering (DLS) is the appropriate analytical method to verify sample homogeneity, detect aggregates and find solvent conditions that prevent aggregation (Mikol, Hirsch & Giegé, 1990; Borgstahl, 2007; Niesen *et al.*, 2008).

4.1.3. Crystallization arrangements and classical methodologies

Many methods can be used to crystallize macromolecules (Ducruix & Giegé, 1999; McPherson, 1982, 1999). They all aim to bring the macromolecules to an appropriate state of supersaturation (Fig. 4.1.3.1). Although vapour-phase equilibrium and dialysis techniques are favoured, batch and free interface diffusion methods are often used. Besides the physical and chemical variables that affect crystallization (Fig. 4.1.1.1), macromolecular crystal growth is influenced by the crystallization method itself and the geometry of the setup. Generally, in current methods, growth is promoted by the non-equilibrium nature of the crystallization process, which seldom occurs at constant protein concentration. This introduces changes in supersaturation and, hence, may lead to changes in growth mechanism. Crystallization at constant protein concentration, however, can be achieved in special arrangements based on liquid circulation cells (Vekilov & Rosenberger, 1998).

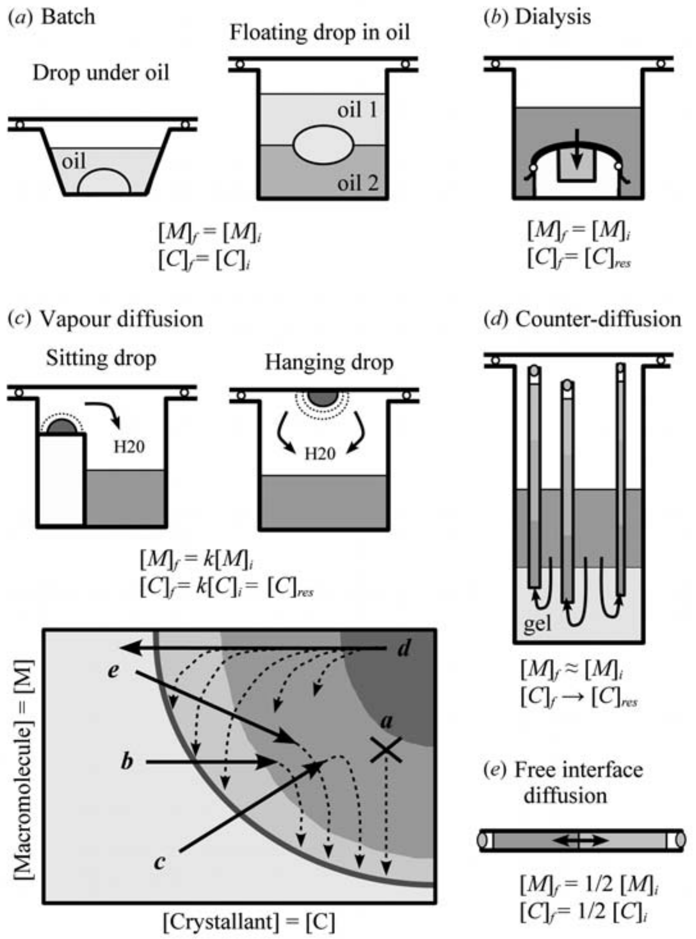


Figure 4.1.3.1

Principles of major methods used to crystallize biological macromolecules. (*a*) Two versions of batch crystallization. (*b*) Dialysis method with Cambridge button. (*c*) Vapour-diffusion crystallization with sitting and hanging drops. (*d*) Counter-diffusion setup in X-ray capillary tubes pinched in a gel layer. (*e*) Crystallization by free-interface diffusion in a capillary where two solutions of equivalent volume are brought into contact. The evolution of the macromolecule concentration, $[M]$, and crystallant concentration, $[C]$, in the different methods is indicated (initial and final concentrations in the crystallization solutions are $[M]_i$, $[M]_f$ and $[C]_i$, $[C]_f$, respectively; $[C]_{\rm res}$ is the concentration of the crystallant in the reservoir, and k is a dilution factor specified by the ratio of the initial concentrations of crystallant in the drop and reservoir. In practice, glass vessels in contact with macromolecules should be silicone-treated in a way to obtain hydrophobic surfaces. Typical equilibration trajectories are illustrated in the phase diagram by black arrows, and the evolution of drops after nucleation and during growth are indicated by dashed arrows.

4.1.3.1. *Historical development of methods*

Protein crystallization is an old field that started more than 100 years ago (McPherson, 1991). Early methods included protein extractions with salts or organic solvents, or dialysis of salt solutions against water, and they were carried out on the gramme scale. Batch crystallization was the method of choice at that time. A first breakthrough that paralleled the development of X-ray methods occurred in the 1960s with the development of micromethods such as dialysis and vapour diffusion (with protein at the 1–100 mg scale and crystallization assays in the 10–50 µl range). However, it became rapidly apparent that screening of the entire

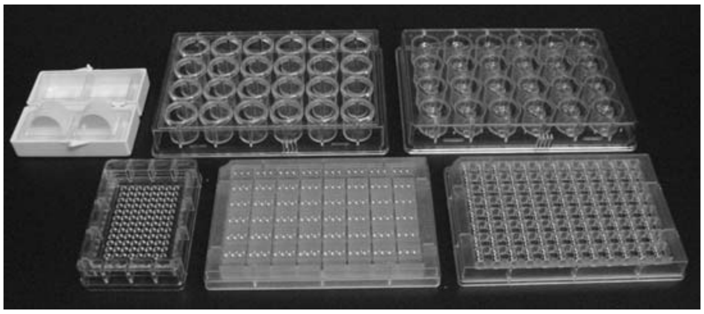

Figure 4.1.3.2
The evolution of crystallization plates from hand-made assays to the high-throughput era. Shown here is an array of crystallization materials and plates. In the upper left is a box of siliconized, glass coverslips used in hanging-drop experiments. Clockwise from the coverslips are a greased VDX plate for hanging-drop experiments, a Cryschem sitting-drop plate, an Intelliplate 96, primarily for use with robotic systems for sitting drops, an Intelliplate 48, and finally, a Vapour–Batch plate that can be used for multiple methods. All of these materials are readily available from commercial sources (photo courtesy of Hampton Research).

crystallization space in searching for appropriate conditions is not feasible in practice. To overcome this difficulty, incomplete factorial methods and other statistical approaches for designing and analysing crystallization experiments were developed (Carter & Carter, 1979; Carter, 1997). A second series of breakthroughs, in the mid-1980s, was stimulated by microgravity research and the advent of structural biology (Giegé *et al.*, 1995). Miniaturization was pursued, molecular biology gave more ready access to samples and more rationality entered the field with, among others, crystallization in gelled media or by counter-diffusion. Moreover, the use of screens was generalized (Jancarik & Kim, 1991) and early robotics facilitated the work of the crystallizers, permitting more extensive screening and yielding improved reproducibility. The last breakthroughs came from structural genomics and have led to further miniaturization (at the nanoscale), more systematic use of robotics and high-throughput screening methods. Finally, advanced methods emerged to produce crystals of better quality (see Section 4.1.4). The size and geometry of crystallization plates recapitulate these methodological developments (Fig. 4.1.3.2).

4.1.3.2. Batch crystallizations

Batch methods are the simplest techniques used to produce protein crystals. They require no more than just mixing the macromolecular solution with crystallants until supersaturation is reached (Fig. 4.1.3.1*a*). Batch crystallization was used to grow crystals in containers of different geometries and samples from the ml to the µl range (McPherson, 1982; Luft *et al.*, 1999*a*). Because one necessarily begins in the supersaturated region of the phase diagram (Fig. 4.1.1.1), nucleation is often excessive. Large crystals, however, can be obtained when the degree of supersaturation is near the metastable region of the crystal/solution phase diagram.

In the early 1990s an automated microbatch crystallization method already allowed the investigation of samples of less than 2 µl (Chayen *et al.*, 1990). In this case, reproducibility is guaranteed. Samples are dispensed and incubated under oil, thus preventing rapid evaporation and uncontrolled concentration changes of the components in the microdroplets. Note, however, that oils are slightly vapour permeable and that the slow evaporation kinetics are dependent on the type of oil (paraffin or silicone oils) used (D'Arcy *et al.*, 1996; Chayen, 1997). The method was adapted for rapid screening of crystallization conditions (D'Arcy, MacSweeney, Stihle & Haber, 2003). It was also adapted for crystallizing proteins in drops suspended between two oil layers (Chayen, 1996; Lorber & Giegé, 1996). Large drops (up to 100 µl) can be deployed allowing easy observation of the crystallization process. Moreover, the absence of contacts between the mother liquor and any solid surfaces results in a lower number of nucleation sites and larger crystals. Note that a hands-free system based on microbatch crystallization in modified X-ray glass capillaries has been developed that allows *in situ* diffraction data collection (Sugahara *et al.*, 2009).

Batch crystallization can also be conducted under high pressure (Lorber *et al.*, 1996) and was adapted for crystallizations on thermal gradients with samples of ~7 µl accommodated in micropipettes (Luft *et al.*, 1999*b*). This latter method permits rapid screening to delineate optimal temperatures for crystallization and frequently yields crystals of sufficient quality for diffraction analysis. Batch methods also permit crystallizations based on thermonucleation (DeMattei & Feigelson, 1993). In a user-friendly version, transfer of crystallization vessels from one thermostated cabinet to another maintained at a higher or lower temperature, depending on whether the protein has normal or retrograde solubility, can readily be done. A variation of classical batch crystallization is the sequential extraction procedure (Jakoby, 1971), based on the property that the solubility of many proteins in highly concentrated salt solutions exhibits significant, but shallow, temperature dependencies.

4.1.3.3. Dialysis methods

Dialysis readily permits easy variation of many parameters that influence protein crystallization. Different types of systems can be used, but all follow the same general principle. The protein is separated from a large volume of solvent by a semi-permeable membrane that allows passage of small molecules, but prevents that of the macromolecules (Fig. 4.1.3.1*b*). Equilibration kinetics depend on the membrane molecular weight exclusion size, the ratio of the concentrations of crystallant inside and outside the macromolecule chamber, the temperature, and the geometry of the dialysis cell. The simplest technique is to use a dialysis bag (*e.g.* of inner diameter ~2 mm), but this usually requires at least 100 µl protein solution per trial.

Crystallization by dialysis has been adapted to small volumes (10 µl or less per assay) in microdialysis cells made from capillary tubes closed by dialysis membranes or polyacrylamide gel plugs (Zeppenzauer, 1971). Microdialysis devices exist in a variety of forms; some are derived from the original Zeppenzauer system (Weber & Goodkin, 1970), others are known as the Cambridge button (Reid *et al.*, 1973) or the microdialysis rod (Lee & Cudney, 2004). With such devices, protein solutions are deposited in 10–50 µl depressions in Plexiglass microdialysis buttons, which are then sealed by dialysis membranes fixed by rubber 'O' rings, and subsequently immersed in a solution contained in the wells of Linbro plates (or other vessels). Wells are sealed with glass coverslips and vacuum grease or tape. In the double-dialysis procedure, the equilibration rate is stringently reduced, thereby improving the method as a means of optimizing crystallization conditions (Thomas *et al.*, 1989). Equilibration rates can be manipulated by choosing appropriate membrane molecular weight exclusion limits, distances between dialysis membranes or relative volumes.

4.1.3.4. Vapour-diffusion methods

Crystallization by vapour diffusion was introduced in structural biology for the preparation of tRNA crystals (Hampel *et al.*, 1968). It is well suited for small volumes (as little as 1 µl or less) and has become the favoured method of many experimenters. It is practised in a variety of forms and is the method of choice for robotic applications. In all of its versions, a drop with the protein to be crystallized, together with buffer, crystallant and additives, is equilibrated against a reservoir containing a solution of crystallant at a higher concentration than that in the drop (Fig. 4.1.3.1*c*). Equilibration proceeds by diffusion of the volatile species until the vapour pressure of the drop equals that of the reservoir. If equilibration occurs by water (or organic solvent) exchange from the drop to the reservoir (*e.g.* initial salt concentration in the reservoir higher than in the drop), it leads to a volume decrease of the drop, so that the concentration of all constituents in the drop increases. The situation is reversed if the initial concentration of the crystallizing agent in the reservoir is lower than that in the drop. In that case, water exchange occurs from reservoir to drop. Crystallization of several macromolecules was achieved using this 'reversed' procedure (Giegé *et al.*, 1977; Richard *et al.*, 1995; Jeruzalmi & Steitz, 1997).

Historically, hanging drops have been deployed in Linbro-type tissue culture plates (Fig. 4.1.3.2). These plates contain 24 wells with volumes of ~2 ml and each well is covered by a glass coverslip sealed with vacuum grease. Drops are composed by mixing 2–10 µl aliquots of the protein with aliquots of the crystallant and additional components, as needed. A variant of the procedure is the HANGMAN method. It utilizes a clear, non-wetting adhesive tape that both supports the protein drops and seals the reservoirs (Luft & De Titta, 1992). Modern arrangements either maintain the 24-well format with more convenient screw-in lids, or adopt the 96-well format with drops deposited on an adhesive sealing tape. The general principle remains the same: a twofold ratio between the concentration of the crystallant in the reservoir and in the drop is most frequently used. This is achieved by mixing a droplet of protein at twice the desired final concentration with an equal volume of the reservoir at the proper concentration (to prevent drops from falling into the reservoir, their final volume should not exceed 15 µl). When no crystals or precipitate are observed in the drops, either sufficient supersaturation has not been reached or only the metastable region has been attained. In the latter case, changing the temperature by a few degrees may be sufficient to initiate nucleation. In the former case, the concentration of precipitant in the reservoir must be increased.

Sitting drops can be dispensed into a variety of different devices. Arrangements consisting of Pyrex plates with a variable number of depressions (up to nine) installed in sealed boxes were used for tRNA crystallization (Dock *et al.*, 1984). Drops of mother liquor are dispensed in the depressions and reservoir solutions with crystallant are poured into the bottom sections of the boxes. These systems are efficient for large drop arrays and can be used for both screening and optimizing crystallization conditions. Multichamber arrangements are suitable for the control of individual assays (Fig. 4.1.3.2). They often consist of polystyrene plates with a variable number of wells (24, 96 and more) that can be individually or collectively sealed. Sitting drops can also be placed on microbridges (Harlos, 1992) or supported by plastic posts in the centres of the wells. Reservoir solutions are contained in the wells in which the microbridges or support posts are placed. Plates with 96 wells, sealed with clear sealing tape, are convenient for large matrix screening. Most of these plates are commercially available and can often be used for a majority of different vapour-diffusion crystallization methodologies (hanging, sitting or sandwich drops, the latter being maintained between two glass plates). A crystallization setup in which drops are deployed in glass tubes, which are maintained vertical and epoxy-sealed on glass coverslips, is known as the plug-drop design (Strickland *et al.*, 1995). Plug-drop units are placed in the wells of Linbro plates surrounded by reservoir solution and then the wells are sealed as usual. With this geometry, crystals do not adhere to glass coverslips as they may with sandwich drops.

Vapour-phase equilibration can be achieved in capillaries (Luft & Cody, 1989) or even directly in X-ray capillaries, as was described for ribosome crystallization (Yonath *et al.*, 1982). This last method may even be essential for fragile crystals, where transferring from crystallization cells to X-ray capillaries or cryo-loops can produce mechanical damage. Vapour-diffusion methods permit easy variations of physical parameters during crystallization, and many successes have been obtained by affecting supersaturation by temperature or pH changes. With ammonium sulfate as the crystallant, it has been shown that the ultimate pH in the drops is imposed by the pH of the reservoir (Mikol *et al.*, 1989). Thus, varying the pH of the reservoir permits adjustment of that in the drops. Sitting drops are also well suited for carrying out epitaxic growth of macromolecule crystals on mineral matrices or other surfaces (McPherson & Shlichta, 1988*a*; Kimble *et al.*, 1998; Stolyarova *et al.*, 2006).

The kinetics of water evaporation (or of any other volatile species) determine the kinetics of supersaturation and, consequently, that of nucleation (Martins, Pëssoa *et al.*, 2008; Martins, Rocha & Damas, 2008). Kinetics measured from hanging drops containing ammonium sulfate, PEG or MPD are significantly influenced by experimental conditions (Mikol, Rodeau & Giegé, 1990; Luft *et al.*, 1996). The parameters that chiefly determine equilibration rates are temperature, initial drop volume (and initial surface-to-volume ratio of the drop and its dilution with respect to the reservoir), water pressure and the chemical nature of the crystallant (Newman, 2005; Newman *et al.*, 2007). The distance separating the drop from the reservoir solution is another critical element and a simple procedure was designed to allow variation of the rate of water equilibration, thereby optimizing crystal-growth conditions (Luft *et al.*, 1996). Evaporation rates can also be monitored and controlled in a weight-sensitive device (Shu *et al.*, 1998). Another method uses oil layered over the reservoir, which permits very slow evaporation of the underlying aqueous solution (Chayen, 1997). The thickness of the oil layer, therefore, dictates evaporation rates and, consequently, crystallization rates (see Section 4.1.3.2).

The period for water equilibration to reach 90% completion can vary from ~25 h to more than 25 d. The most rapid equilibration occurs with ammonium sulfate, more slowly with MPD, while that with PEG is by far the slowest. An empirical model has been proposed which estimates the minimum duration of equilibration under standard experimental conditions (Mikol, Rodeau & Giegé, 1990). Equilibration, which brings the macromolecules very slowly to a supersaturated state, may explain the crystallization successes with PEG as the crystallant. This explanation is corroborated by experiments showing an increase of the terminal crystal size when equilibration rates are reduced (Chayen, 1997).

4.1.3.5. Free-interface and counter-diffusion methods

In these methods, equilibration occurs by direct diffusion of the crystallant into the protein solution (Salemme, 1972; Garcia-Ruiz & Moreno, 1994). Both methods require minimal convection and, therefore, experiments are conducted in capillaries (Fig. 4.1.3.1*d*,*e*). To avoid too rapid mixing in a free-interface diffusion assay, the less dense solution is poured gently on the densest one. One can also freeze the solution with the crystallant and layer the protein solution on top. The components of each solution in contact will then diffuse into the other compartment.

A more versatile version of this technique is counter-diffusion crystallization (Garcia-Ruiz, 2003; Ng *et al.*, 2003; Otálora *et al.*, 2009), which was referred to as the 'gel acupuncture' method in its first version (Garcia-Ruiz & Moreno, 1994). In a typical experiment, a gel base is formed from agarose or silica in a small container, and a concentrated crystallant solution is poured over its surface. This crystallizing agent permeates the gel by diffusion, forming a gradient. A capillary filled with the protein is inserted into the gel. The crystallant then enters the capillary from the gel and forms an upward gradient in the capillary, promoting crystallization along its length as it rises by pure diffusion. The method operates with a variety of gels and crystallants, with different heights of these agents over the gel and with open or sealed capillaries. It has already been successfully used to crystallize a variety of macromolecules, some of very large size (Garcia-Ruiz *et al.*, 1998; Biertümpfel *et al.*, 2002; Kutá Smatanová *et al.*, 2006).

The main advantage of the counter-diffusion technique is that a wide range of supersaturation conditions is tested in a single experiment. While a precipitate may form at the entrance of the capillary at high supersaturation, monocrystals may grow at the opposite end where supersaturation is lower. A second advantage is that all steps from crystallization to structure solution, including substrate/cryoprotectant/heavy atoms soaking and X-ray analysis can be performed without any crystal handling (Gavira *et al.*, 2002). In recent versions, the diameter and length of counter-diffusion capillaries have been reduced so that assays can be conducted at a 300 nl scale (see Section 4.1.4.1.).

4.1.3.6. Miniaturization, automation and robotics

The first user-friendly attempt to miniaturize and automate crystallization concerned batch crystallization in microdroplets under oil (Chayen *et al.*, 1990). In recent years, robots and other automated instruments, and entire integrated systems, have been developed to accelerate the crystallization process (DeLucas *et al.*, 2003; Hosfield *et al.*, 2003; Luft *et al.*, 2003; Bard *et al.*, 2004; Berry *et al.*, 2006) and the optimization procedures (Newman *et al.*, 2008). They have the capacity to screen thousands of crystallization conditions, and they do so precisely and reliably, with fewer errors and better record keeping than most humans. In many large laboratories, these have become essential pieces of equipment. Using standard, usually commercially available, screening kits, sometimes supplemented by local preferences or family-directed screens, they can often arrive at acceptable crystals in the most expeditious manner possible.

Robotic systems are efficient, tireless and accurate, but they offer another important feature in addition. They can carry out experiments using drop samples of very small volume, drops of 1 µl in most cases, nanolitres in some. This, in turn, produces a requirement for automated, microphotographic visualization instruments, and complex storage and handling systems, and their associated expense. On the other hand, a great advantage emerges in that they can perform enormous numbers of crystallization trials using remarkably little biological sample. This, in turn, relieves the investigator of a significant burden in terms of preparing and purifying macromolecules.

Many of the robotic systems are based on reproducing procedures currently used for manual experiments, such as sitting and hanging drops, and microdrops under oil. They are simply carried out on a much smaller scale. More recently, however, even more miniaturized devices have come on the market. These use what is now commonly called nanotechnology to manipulate small amounts of liquids and fluid streams. These devices are only now seeing rigorous evaluation in laboratories, but they clearly show great promise for the future (see Section 4.1.4). Another effort is underway to develop robotic systems for crystal harvesting and crystallization devices that will allow direct X-ray exposure of crystals where they are grown *in situ* (Viola *et al.*, 2007). These would obviate the need for careful mounting, an often-problematic aspect of data collection.

4.1.4. Advanced crystallization methodologies

In methods that manipulate physical parameters, the effects on crystallization are manifold. Among others, they may influence fluid properties in the crystallization media and movement of molecules (gravity), alter the conformation of the macromolecule (pressure), orient crystals (magnetic field), or influence nucleation (electric field). Thus, initiation of crystallization may be triggered by various mechanisms, growth may be differently influenced and, in favourable cases, crystal quality improved.

4.1.4.1. Crystallization in convection-free media

Theoretical considerations. When a crystal starts to grow, it attracts surrounding molecules and creates a concentration gradient. Since crystallization occurs on earth in the gravity field, this gradient of concentration and density will lead to convective currents in the mother liquor. In addition, as soon as the crystal becomes big enough, it will sink to the bottom of the solution. Convection and sedimentation almost always take place in classical experimental setups and they almost certainly influence crystallization processes. Their contribution would be drastically reduced in the absence of gravity, as occurs in weightlessness, and the theory predicts more regular crystal growth under a microgravity–diffusive regime that should favour enhanced crystal quality. Such considerations have justified space-crystallization programmes and, as a consequence, have contributed to a deeper understanding of the crystallization process of biomacromolecules (Giegé *et al.*, 1995; McPherson, 1996; Kundrot *et al.*, 2001). However, because of limited access to space experimentation, crystallization in weightlessness will never be user friendly. This has stimulated studies for finding easy ways to simulate microgravity conditions in the laboratory. Such methods, where crystal growth is less dependent on convection and more on diffusion, take advantage of gelled media and microfluidic environments.

Use of microgravity. The first observation in microgravity was that the absence of sedimentation permits the growth of individual crystals in suspension, without any perturbation by contact with vessel walls and neighbouring crystals. However, one should bear in mind that even in microgravity small accelerations can occur owing to vehicle movement and crystal displacement has been recorded (*e.g.* Lorber *et al.*, 2000). Microgravity experiments require specific instrumentation with dedicated reactors based on current batch, dialysis and vapour-diffusion methods, or on more microgravity-relevant approaches, such as free-interface or counter-diffusion, with crystallization vessels often of rather large size (DeLucas *et al.*, 1994; Giegé *et al.*, 1995; McPherson, 1996; Gonzalez-Ramirez, Carrera *et al.*, 2008). Reproducible data, with a substantial number of model proteins (lysozyme, thaumatin, canavalin and several plant viruses), were obtained in the versatile Advanced Protein Crystallization Facility instrument from the European Space Agency (Vergara *et al.*, 2003, 2005). Altogther, an overall positive effect of microgravity on protein crystal growth emerged.

In support of this conclusion are observations of larger sizes for space-grown crystals and improved optical quality, as exemplified by thaumatin crystals (Ng, Lorber *et al.*, 1997). The maximum resolution of diffraction patterns also indicated superiority for microgravity crystals. A striking example is parvalbumin that diffracts to 0.9 Å resolution, while the earth-grown crystals are not suitable for diffraction analysis (Declercq *et al.*, 1999). Also, in several instances, the signal-to-noise ratio of X-ray diffraction data collected from space crystals was greater than for the corresponding earth controls, as for satellite tobacco mosaic virus (McPherson, 1996) and thaumatin (Ng, Lorber *et al.*, 1997; Lorber, Sauter, Robert *et al.*, 1999). An additional criterion is the reduced mosaic spread of reflections recorded from space samples (Snell *et al.*, 1995; Stojanoff *et al.*, 1996; Ng, Lorber *et al.*, 1997; Lorber, Sauter, Robert *et al.*, 1999). Impurity incorporation during growth is another issue and, as shown with lysozyme, the microgravity-grown crystals incorporate fewer impurities than the earth controls (Carter *et al.*, 1999). The best criterion for enhanced crystal quality, however, is the crystallographic structure. In a case study with lysozyme, significant improvement of resolution from 1.6 to 1.35 Å, decreased atomic displacement parameters (ADPs or B factors) and a structure of increased clarity have been noted for the space-grown crystals (Carter *et al.*, 1999). In another study on an aspartyl-tRNA synthetase, a strictly comparative analysis showed that crystals grown in microgravity were superior in many respects to controls prepared under otherwise identical conditions on earth, facilitating structure determination at 2.0 Å resolution (Ng *et al.*, 2002).

Nevertheless divergent conclusions were reached concerning the quality of the X-ray structure, which was shown to be improved (Carter *et al.*, 1999) or unaffected (Vaney *et al.*, 1996) by microgravity. This contradiction may originate from different levels of impurities present in the protein samples and/or from non-identical growth conditions in different hardware. Conceivably, alteration by gravity of fluid properties could affect nucleation. Transport is of importance, because the large sizes of proteins imply that they have low diffusivities. Elimination of fluid convection may, however, dramatically affect the movement and distribution of proteins in the fluid and their transport and absorption to crystal surfaces. In addition, many proteins form non-specific aggregates in solution. These may be a major source of the contaminants that are incorporated into crystal lattices. By virtue of their size and low diffusivity, the movement of aggregates and large impurities in solution is even more significantly altered.

On earth there is continuous density-driven convective mixing in the solution due to gradients arising from temperature or from incorporation of molecules by the growing crystal. The effects of diffusive transport in the laboratory are, by comparison with the microgravity case, almost negligible because of the very slow rate of diffusion of large proteins. Because of convective mixing, protein crystals nucleated on earth are continuously exposed to the full concentration of protein nutrient present in the bulk solvent. Convection thus maintains, at the growing crystal interface, excessive supersaturation as growth proceeds. This provides an explanation as to why microgravity may improve the quality of protein crystals. The mechanism for enhanced order and reduction of defects may not be directly due to convective turbulence at growing crystal surfaces, but to reduction of the concentration of nutrient molecules and impurities in the immediate neighbourhood of the growing crystals. As a protein crystal forms in microgravity, a concentration gradient or 'depletion zone' is established around the nucleus. Because protein diffusion is slow and that of impurities may be even slower, the depletion zone is quasi-stable. The net effect is that the surfaces of the growing crystal interface with a local solution phase at a lower concentration of protein nutrient and impurities than exists in the bulk solvent. The crystal, as it grows, experiences a reduction in its local degree of supersaturation and essentially creates for itself an environment equivalent to the metastable region where optimal growth is expected.

Investigations of protein crystallization diverged along two paths. The objective of the first was to produce high-quality crystals for X-ray diffraction analysis. The crystals themselves were the product of the space-bound experiment and biochemical results were secondary. The goal of the second line of investigation was to understand and to control the physics of the process. This second interest was supported by extensive ground-based research. The confluence of results yielded persuasive explanations for the observed improvements in size and quality of protein crystals grown in microgravity and a robust theoretical framework for understanding the phenomena involved. They showed also that protein crystals are more sensitive to the very high degrees of supersaturation at which they are usually grown and to the mass-transport mechanisms responsible for bringing nutrient to their growing surfaces. The self-regulating nature of protein crystallization in microgravity, through the establishment of local concentration gradients of reduced supersaturation, explains why the diffusive transport that predominates produces a significant difference in ultimate crystal quality.

Crystallization in gelled media. Because convection occurs in free solutions, crystallization in gels represents what is essentially a convection-free environment (Henisch, 1988). Thus, the quality of crystals may be improved in gels. Whatever the mechanism of crystallization in gels, the procedure will produce changes in the nucleation and crystal-growth processes, as has been verified with many proteins (Robert & Lefaucheux, 1988; Cudney *et al.*, 1994; Vidal *et al.*, 1999; Biertümpfel *et al.*, 2002; Lorber *et al.*, 2009). Two types of gels have been used, namely, agarose and silica gels. The latter seem to have proven the most adaptable, versatile and useful for proteins. With both agarose and silica gels, it is possible to use a variety of different crystallants, including salts, organic solvents and polymers such as PEG (Gonzalez-Ramirez, Caballero & Garcia-Ruiz, 2008). They also allow the investigator to control pH and temperature. The most successful efforts have involved direct diffusion arrangements, where the crystallant is diffused into a protein-containing gel or *vice versa*. In practice, experiments are conducted in semi-liquid gelled media where the agarose concentration does not exceed 0.6%(w/v), but crystallization can also take place in 2.0%(w/v) agarose viscoelastic gels, a condition that does not affect the crystal structures (Sugiyama *et al.*, 2009).

Crystals grown in gels can easily be removed from their soft environment and set up for X-ray analysis. They tend to be robust since, as shown with lysozyme crystals, agarose fibres are incorporated into the crystal lattice (Gavira & Garcia-Ruiz, 2002). Gel

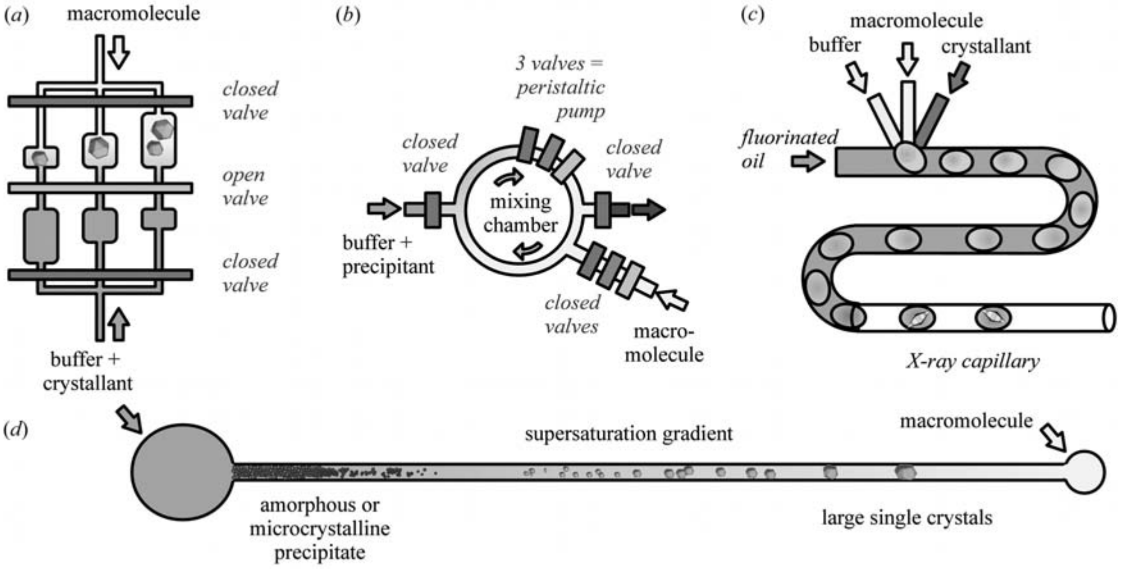

Figure 4.1.4.1
Examples of microfluidic devices designed for biocrystallization. (*a*) Schematic view of one of the 46 modules composing the free-interface diffusion chip. An integrated fluidic circuit dispenses the macromolecule and crystallant solutions into the final chambers. The microchannels are then closed and those connecting the top and bottom chambers are opened with the help of pneumatic valves integrated in the chip. The crystallant diffuses in the protein chamber and triggers crystallization. In this version of the chip, each module is divided into three pairs of chambers with volumes of 5–20 nl to create different protein-to-crystallant concentration ratios. (*b*) The mixing rotor of a formulation chip designed for the high-throughput study of precipitation diagrams. This chip generates protein/buffer/crystallant mixtures at different concentrations in its 5 nl rotor. The three valves in a row constitute a peristaltic pump that homogenizes the mixture. A charge-coupled device (CCD) camera is used to detect the appearance of a precipitate. (*c*) The nanobatch chip. Nanodroplets are produced in a microfluidic channel and displaced by inert oil (the flow rate determines the drop size from 10 to 20 nl). Droplets can be stored in the chip or in capillaries connected to the exit of the chip. They can be inspected and crystals can be characterized by X-ray diffraction. (*d*) Microfluidic chip for counter-diffusion experiments. This method relies on the diffusion of a crystallant into an elongated chamber (the microfluidic channel) containing a macromolecular solution. A concentration gradient is generated that develops along the entire crystallization chamber. The propagating supersaturation wave of gradually decreasing amplitude tests a broad range of nucleation and growth conditions in a single experiment. While a precipitate may form at the entrance of the chamber, monocrystals may grow at the opposite end. Crystals can be observed and analysed by X-ray diffraction directly inside the chip (adapted from Sauter *et al.*, 2007).

growth, because it suppresses convection, has proven to be a useful technique for analysing concentration gradients around growing crystals by interferometric techniques (Robert *et al.*, 1994) and growth mechanisms by differential interference contrast microscopy (Van Driessche, Otalora, Gavira & Sazaki, 2008). In conclusion, gelled media mimic microgravity conditions, preserve crystals once they are grown and, as expected, crystals grown in gels are often of superior quality to controls grown from solutions (Zhu *et al.*, 2001; Moreno *et al.*, 2002; Sauter *et al.*, 2002). Finally, gels can prevent damage during crystal soaking and cryo-cooling (Biertümpfel *et al.*, 2005; Sauter *et al.*, 2009; Lorber *et al.*, 2009).

Crystallization in microfluidic devices. Microfluidic devices were recently introduced in the field of biological crystal growth and represent a new means of crystallizing under diffusive conditions. These systems were primarily intended to miniaturize and to parallelize crystallization assays, thus leading to novel, cost-effective, high-throughput screening approaches. However, because of the small size of their channels and chambers (typically below 100 µm in depth and width), they also provide a diffusive environment comparable to that existing in a capillary tube, in a gel, or under microgravity.

Indeed, the first microfluidic application in biocrystallization was a miniaturized version of the free-interface diffusion technique in which the absence of convection is essential (Hansen *et al.*, 2002). The chip consists of a complex integrated fluidic circuit including two networks of channels, one for liquid handling and a second serving as actuation valves. The chip is dedicated to high-throughput screening and, in its initial version, was designed to test 48 crystallization conditions with less than 10 µl of sample solution. Three parallel sets of chambers are used to bring into contact different proportions of macromolecule and crystallant solutions (Fig. 4.1.4.1*a*). This concept of chip was further modified to combine free-interface diffusion with vapour diffusion (or vapour permeation) for fine tuning the supersaturation achieved in crystallization chambers (Hansen *et al.*, 2006). This technology also led to a 'formulator chip' that can perform hundreds of mixing operations in just a few hours in order to establish precipitation diagrams (Fig. 4.1.4.1*b*). A single assay consumes less than 5 nl sample/buffer/precipitant solution and derived precipitation maps are used to delineate a grid of conditions for crystallization screening (Hansen *et al.*, 2004).

The second crystallization method implemented in microfluidics was 'batch in nanodroplets' (Zheng *et al.*, 2003). The chip design is extremely simple: it consists of inlets for protein, buffer and crystallant solutions, and a microfluidic channel in which 10 nl droplets are prepared by mixing these solutions in various ratios. This device allows a daily formulation of thousands of nanodrops or plugs (Fig. 4.1.4.1*c*), which are carried by a flow of inert fluorocarbon oil. They are stored on the chip or in capillary tubes plugged at the exit of the chip and their content can easily be analysed by X-ray diffraction (Yadav *et al.*, 2005). This method is very well suited for high-throughput screening and, in addition to crystal growth, this technology can be used for many applications in chemistry (Song *et al.*, 2006).

Based on the nanodrop approach, a more complex system has recently been designed for basic research purposes. It is able to formulate droplets and to flow them to storage chambers where they can be concentrated or diluted by water permeation through the chambers' walls. This 'phase chip' is designed to establish phase diagrams with total control over supersaturation, nucleation and growth kinetics in each individual drop (Shim *et al.*, 2007).

As for free-interface diffusion, the absence of convection in microfluidic channels makes microsystems very appealing for implementing counter-diffusion experiments (Sauter *et al.*, 2007; Ng *et al.*, 2008). Characteristic counter-diffusion features were successfully reproduced in microchannels with a production of crystalline material ranging from microcrystals to large monocrystals along the supersaturation gradient. When made of appropriate polymer material, these counter-diffusion chips also allow a direct on-chip characterization of the crystals by X-ray diffraction, without any further (and potentially deleterious) sample handling (Ng *et al.*, 2008; Dhouib *et al.*, 2009).

These examples illustrate the many advantages of microfluidic chips – low sample consumption, high-throughput screening capabilities, quasi-ideal convectionless growth conditions – and one can anticipate that microfluidic technology will become a popular and affordable tool both for condition screening, optimization and X-ray analysis, and for basic crystallogenesis research.

Simulating other aspects of microgravity crystal growth. Heterogeneous nucleation or crystal growth on the solid surface of crystallization vessels can be avoided under levitation (Rhim & Chung, 1990) and more easily in batch between two oil layers (Chayen, 1996; Lorber & Giegé, 1996). This can also be achieved for the growth of large protein crystals by mild stirring of the solution in two-liquid systems (Adachi *et al.*, 2004).

It was conjectured that other features of weightlessness, such as suppression of convection, could be achieved in the laboratory under hypergravity and when magnetic or electric fields are applied. These possibilities have been tested experimentally. Crystals were grown under forced diffusive transport of the macromolecules in centrifuges (Karpukhina *et al.*, 1975; Lenhoff *et al.*, 1997; Lorber, 2008) and nucleation was shown to be affected by magnetic (Ataka *et al.*, 1997; Sazaki *et al.*, 1997) or external electric (Taleb *et al.*, 1999; Nanev & Penkova, 2001) fields. Interestingly, under these last conditions, growing crystals were shown to have preferential orientations and specific spatial distributions in the crystallization chambers. Magnetic fields produced by small permanent magnets of 1.25 T are sufficient to produce these effects (Astier *et al.*, 1998) and numerical predictions revealed that magnetization forces could damp convection (Qi *et al.*, 2001). For crystallization induced by electric fields, simple devices adapted to vapour-diffusion (Charron *et al.*, 2003) and batch (Al-Haq *et al.*, 2007) methods are available. Crystallization can also be electrochemically assisted by internal electric fields (Frontana-Uribe & Moreno, 2008). In some cases, magnetic and electric fields have been coupled and experiments conducted in gelled media (Sazaki *et al.*, 2004; Moreno *et al.*, 2009).

Although the above methods are not widespread and the underlying physics not completely validated, they can be useful in special cases. For instance, when crystallization attempts systematically yield showers of microcrystals, crystallization inside electric or magnetic fields can be an alternative to obtain monocrystals suitable for X-ray data collection, because the number of nucleation sites is reduced and can be controlled (Moreno & Sazaki, 2004; Hammadi *et al.*, 2009) and crystal quality maintained (Sato *et al.*, 2000; Lübbert *et al.*, 2004).

4.1.4.2. Methods making use of temperature and pressure

Temperature and pressure are familiar thermodynamic parameters. Indeed, many living organisms are thermophiles, even hyperthermophiles, or barophiles/piezophiles and thus have evolved macromolecules stable at temperatures up to 110 °C or pressures up to 100 MPa, *i.e.* 1000-fold atmospheric pressure (Abe & Horikoshi, 2001). Temperature can trigger nucleation, regardless of the crystallization method. This can be done in a controlled manner, but often occurs as an unexpected consequence of accidental temperature variation in the laboratory. Dedicated systems have been designed for temperature-dependent control of nucleation and growth (Astier & Veesler, 2008), and find application for, among other things, the growth of large high-quality protein crystals for neutron crystallography (Budayova-Spano *et al.*, 2007).

Pressure, as anticipated, can trigger nucleation and sustain protein crystal growth (*e.g.* Suzuki *et al.*, 2002). To facilitate analysis of crystallization output, assays under pressure can be done in agarose gel (Kadri *et al.*, 2003). Rather simple equipment is required allowing batch crystallization of ~12 individual samples of ~80 µl that can be collectively pressurized up to ~400 MPa (Lorber *et al.*, 1996). The effects exerted by pressure are multiple and protein dependent, with habit, number, length, shape and solubility of crystals modified under pressure. Further, crystallization volumes and diffraction properties are affected and, interestingly, these physical properties are essentially conserved upon depressurization of the crystals. In particular, differences in the water sites surrounding thaumatin crystals grown at 0.1 and 150 MPa have been observed (Charron *et al.*, 2002). Crystallographic analysis of cowpea mosaic virus crystals compressed at 330 MPa in a diamond-anvil cell demonstrated pressure-induced ordering of the crystals, lower ADPs and a larger number of ordered water molecules (Girard *et al.*, 2005; Lin *et al.*, 2005).

4.1.4.3. Methods making use of crystallization chaperones

Another strategy that has been used for recalcitrant proteins is to combine them in some manner with a second protein, sometimes called a cocrystallization or chaperone protein (Warke & Momany, 2007; Koide, 2009), so that the complex of the two provides an additional chance for success. The idea was first tested with lysozyme complexed with an Fab antibody fragment (Boulot *et al.*, 1988) and has been used particularly with membrane proteins and antibody domains directed against the target protein (Ostermeier *et al.*, 1995). In those cases the antibody fragment enhanced the solubility of the otherwise hydrophobic protein and provided additional lattice contacts in the resultant crystals. There is, in principle, no reason why such 'crystallization chaperones' could not be used with soluble proteins. Likewise the method can be useful for the crystallization of functional RNA fragments (Ye *et al.*, 2008). An alternate possibility with great potential is the recently developed DARPin technology based on the natural ankyrin repeat protein fold with randomized surface residue positions allowing specific binding to virtually any target protein (Sennhauser & Grütter, 2008).

4.1.4.4. Seeding

It is often necessary to reproduce crystals grown previously, where either the formation of nuclei is limiting, or spontaneous nucleation occurs at such a profound level of supersaturation that poor growth results. In such cases, it is desirable to induce growth in a directed fashion at low levels of supersaturation. This can be accomplished by seeding a metastable, supersaturated protein solution with crystals from earlier trials. Seeding also permits one to uncouple nucleation and growth. Seeding techniques fall into two categories that employ either macroseeds (Thaller *et al.*, 1985) or microcrystals as seeds (Stura *et al.*, 1999; Bergfors, 2003). In both cases, the solution to be seeded should be only slightly supersaturated so that controlled growth can occur.

When seeding with crystals large enough to be manipulated under a microscope, the most important consideration is to eliminate spurious nucleation by transfer of too many seeds. This drawback may be overcome using laser tweezers, a technique that permits non-mechanical, *in situ* manipulation of individual seeds as small as 1 µm (Bancel *et al.*, 1998). Even if a single large crystal is employed, microcrystals adhering to its surface may be carried across to the fresh solution. To avoid this, the macroseed is washed by passing it through a series of intermediate transfer solutions. In doing so, not only are microcrystals removed, but if the wash solutions are chosen properly, some limited dissolution of the seed surface may take place. This has the effect of freshening the seed-crystal surfaces and promoting new growth once it is introduced into the new protein solution. Note that crystals of homologous macromolecules can serve as seeds (Thaller *et al.*, 1985).

In the second approach with microcrystals, the danger is that too many nuclei will be introduced into the fresh supersaturated solution, and masses of crystals will result. To overcome this, a stock solution of microcrystals is serially diluted over a very broad range. Some dilution sample in the series will, on average, have no more than one microseed per ml; others will have several times more, or none at all. An aliquot (~1 µl) of each sample in the series is then added to fresh crystallization trials. This empirical test, ideally, identifies the correct sample to use for seeding by yielding only one or a small number of single crystals when crystal growth is completed. Microseeds can be introduced into crystallization trials at any stage of microbatch or vapour-diffusion experiments (D'Arcy, MacSweeney & Haber, 2003; D'Arcy *et al.*, 2004) and this process can be automated (D'Arcy *et al.*, 2007; Newman *et al.*, 2008; Khurshid *et al.*, 2010).

4.1.5. From the macromolecule to perfect crystals: the physics view

Each of the four stages in crystallization (prenucleation, nucleation, growth and cessation of growth) can be monitored by specific physical techniques. Although systematic characterization of crystallization is usually not carried out in practice, characterization of individual steps and measurement of the physical properties of crystals obtained under various conditions may help in the design of appropriate experimental conditions to reproducibly obtain crystals of a desired quality (*e.g.* of larger size, improved morphology, increased resolution or greater perfection).

4.1.5.1. Prenucleation and nucleation

DLS relies on the scattering of monochromatic light by aggregates or particles moving in solution. Since diffusivity of the particles is related to their size by the Stokes–Einstein equation, measurement of diffusion coefficients can be translated into hydrodynamic radii. By making measurements as a function of scattering angle, information regarding aggregate shape can also be obtained. For single-component systems, the method for determining the size of macromolecules, viruses and larger particles up to a few µm is straightforward. For polydisperse and concentrated systems, the problem is more complex, but with the use of auto-correlation functions and advances in signal detection, DLS provides good estimates of aggregate size distribution and supplies a diagnostic tool for quality control of proteins and optimization of crystallization conditions. Experimental necessity encouraged the design of dedicated instruments for protein crystallization, combining *e.g.* imaging of crystals and DLS analysis within crystallization droplets (Dierks *et al.*, 2008).

In biocrystallogenesis, investigations based on light scattering have been useful in detecting nucleation prior to the appearance of crystals observable under the light microscope, that is, in understanding prenucleation and nucleation. Many studies have been carried out with lysozyme as the model (Kam *et al.*, 1978; Durbin & Feher, 1996), though not exclusively, and they have been developed with two objectives. One is to analyse the kinetics and the distribution of molecular aggregate sizes as a function of supersaturation. The idea is to understand the nature of prenuclear clusters that form in solution and how they transform into crystal nuclei (Kam *et al.*, 1978; Georgalis *et al.*, 1993; Malkin & McPherson, 1994). Such a quantitative approach has sought to define the underlying kinetic and thermodynamic parameters that govern the nucleation process.

A more practical objective is to use light-scattering methods to predict which combinations of crystallants, additives and physical parameters are most likely to lead to the nucleation and growth of crystals (Mikol, Hirsch & Giegé, 1990; Ferré-D'Amaré & Burley, 1997; Borgstahl, 2007; Wilson, 2003; Niesen *et al.*, 2008). A major goal here is to reduce the number of empirical trials. The analyses depend on the likelihood that precipitates are usually linear, branched and extended in shape, since they represent a kind of random polymerization process (Kam *et al.*, 1978). Aggregates leading to nuclei, on the other hand, tend to be more globular and three dimensional in form. Thus, mother liquors that indicate a nascent precipitate can be identified as a failure, while those that have the character of globular aggregates hold promise for further exploration and refinement. Other analyses have been based on discrimination between polydisperse and monodisperse protein solutions, which suggests that polydispersity hampers crystallization, while monodispersity favours it (Mikol, Hirsch & Giegé, 1990).

A more quantitative approach is based on measurement of the second virial coefficient B2, which serves as a predictor of the type of interaction between macromolecules occurring in solution. Using static light scattering, it was found that mother liquors that invariably yield crystals have second virial coefficients that fall within a narrow range of small negative values. Correlations between the associative properties of proteins in solution, their solubility and the B2 coefficient were highlighted (*e.g.* George *et al.*, 1997; Wilson, 2003), and seem to be a general feature. This is a powerful diagnostic of crystallization conditions.

Related methods, such as fluorescence spectroscopy (Crosio & Jullien, 1992; Forsythe *et al.*, 2006), osmotic pressure (Bonneté *et al.*, 1997; Neal *et al.*, 1999), small-angle X-ray scattering (Finet *et al.*, 1998) and small-angle neutron scattering (Ebel *et al.*, 1999; Gripon *et al.*, 1997; Minezaki *et al.*, 1996; Vidal *et al.*, 1998), were used to investigate specific aspects of protein interactions under precrystallization conditions and produced, in several instances, complementary answers to those from light-scattering studies.

4.1.5.2. Growth and cessation of growth

A number of microscopies and other optical methods can be used for studying the crystal growth of proteins (Van Driessche, Otalora, Sazaki *et al.*, 2008). These are time-lapse video microscopy with polarized light, Schlieren and phase-contrast microscopy, Mach–Zehnder and phase-shift Mach–Zehnder interferometry, Michelson interferometry, electron microscopy (EM), atomic force microscopy (AFM) and laser confocal microscopy with differential interference contrast microscopy. Each of these methods provides complementary data which, in combination, have yielded answers to many relevant questions.

Time-lapse video microscopy has been used to measure growth rates (Koszelak & McPherson, 1988; Lorber & Giegé, 1992; Zhu *et al.*, 2001). It was valuable in revealing unexpected phenomena, such as capture and incorporation of microcrystals by larger crystals, contact effects, consequences of sedimentation, flexibility of thin crystals, fluctuations in growth rates and initiation of twinning (Koszelak *et al.*, 1991). Optical microscopy and interferometric methods gave information on concentration gradients that appear as a consequence of incorporation of molecules into the solid state. These methods, however, suffer from rather shallow response dependence with respect to protein concentration. This can be overcome by the introduction of phase-shift methods, as has been successfully achieved in the case of Mach–Zehnder interferometry. With this technique, gradients of protein concentration have been mapped in the mother liquor and around growing crystals. Classical Mach–Zehnder interferometry has been used to monitor diffusion kinetics and supersaturation levels during crystallization, as was done in dialysis setups (Snell *et al.*, 1996) or in counter-diffusion crystal growth cells (Garcia-Ruiz *et al.*, 1999). Using laser confocal microscopy combined with differential interference contrast microscopy it was possible to visualize dislocations in protein crystals during growth (Sazaki *et al.*, 2005). Single-molecule visualization techniques gave access to direct observation of the diffusion of individual fluorescence-labelled protein molecules at an interface between a solution and a protein crystal (Sazaki *et al.*, 2008).

Michelson interferometry can be used for direct growth measurements on crystal surfaces (Komatsu *et al.*, 1993). It depends on the interference of light waves from the bottom surface of a crystal growing from a reflective substrate and the top surface, which is developing and, therefore, changes as a function of time with regard to its topological features. Because growth of a crystal surface is generally dominated by unique growth centres produced by dislocations or two-dimensional nuclei, the surfaces and the resultant interferograms change in a regular and periodic manner. Changes in the interferometric fringes with time provide accurate measures of the tangential and normal growth rates of a crystal (Vekilov *et al.*, 1993; Kuznetsov *et al.*, 1995; Kurihara *et al.*, 1996). From these data, one can determine the surface free energy and the kinetic coefficients that underlie the crystallization process.

EM (Durbin & Feher, 1990) and especially AFM (McPherson *et al.*, 2004) are powerful techniques for the investigation of crystallization mechanisms and their associated kinetics. The power of AFM lies in its ability to investigate crystal surfaces *in situ*, while they are still developing, thus permitting one to directly visualize, over time, the growth and change of a crystal face at near-nanometre resolution. The method is particularly useful in delineating the growth mechanisms involved, identifying dislocations, recording the kinetics of the changes and directly revealing impurity effects on the growth of protein crystals (Konnert *et al.*, 1994; Malkin *et al.*, 1996; Nakada *et al.*, 1999) (Fig. 4.1.5.1). AFM was also applied for the visualization of growth characteristics of crystals made of viruses (Malkin *et al.*, 1995) and RNA (Ng, Kuznetsov *et al.*, 1997). A noteworthy outcome of such studies was the sensitivity of growth to minor temperature changes. A variation of 2–3 °C was sufficient to transform the growth mechanism of yeast tRNA$^{\text{Phe}}$ from spiral screw dislocation growth at low supersaturation to two-dimensional island formation at high supersaturation (Ng, Kuznetsov *et al.*, 1997).

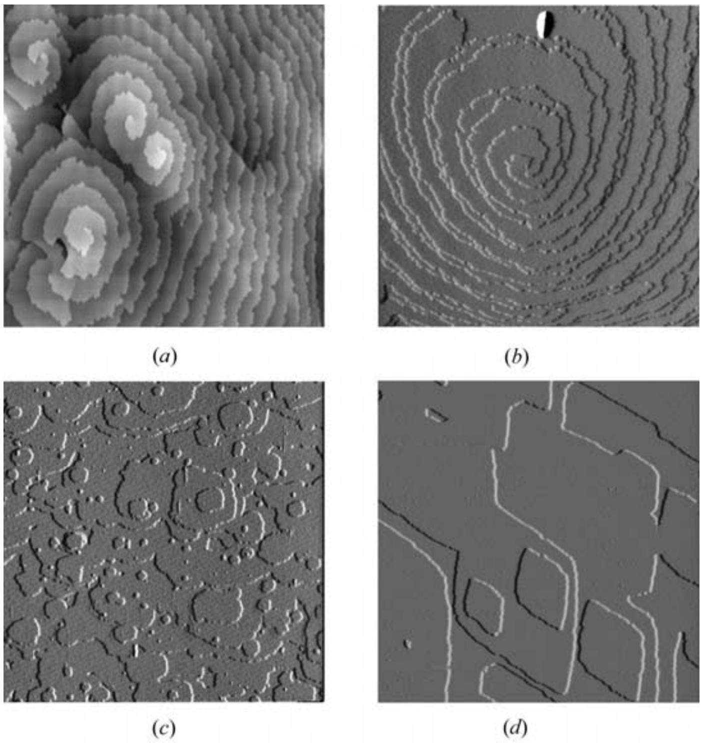

Figure 4.1.5.1
Growth mechanisms and visualization of protein crystal surfaces by AFM. In (*a*) and (*b*) are images of screw dislocations on the surfaces of crystals of the proteins canavalin and trypsin, respectively. The scan areas are 10 µm^2 in (*a*) and 30 µm^2 in (*b*). Screw dislocation growth predominates at low supersaturation. In (*c*) and (*d*) are examples of crystal growth by the formation of two-dimensional islands on the surfaces of crystals of the proteins thaumatin and glucose isomerase, respectively. The scan areas are 20 µm^2 in (*c*) and 11 µm^2 in (*d*). Growth by two-dimensional island formation and spread dominates at higher supersaturation.

4.1.5.3. Uncoupling nucleation and growth, and the constant-growth regime

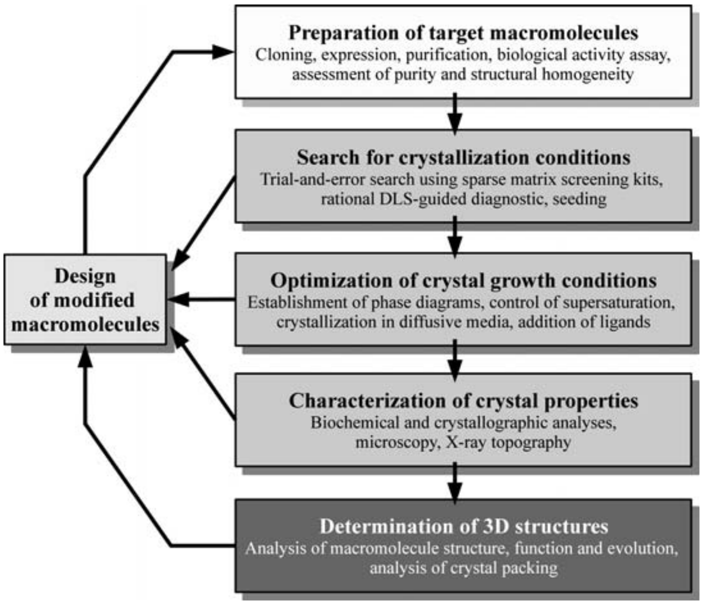
The preparation of high-quality protein crystals should preferentially occur at lowest supersaturation and under a constant-growth regime. Achieving this aim with conventional crystallization methods is *a priori* not easy since growth of crystals is accompanied by a decrease of supersaturation in the crystallization medium (see the trajectory of crystal/solution equilibration in a phase diagram, Figs. 4.1.1.1 and 4.1.3.1). The implication is that it is possible to change the growth regime during the course of the crystallization process, as could be seen by AFM (Ng, Kuznetsov *et al.*, 1997). Such a change will perturb crystal formation and probably accounts for the frequently observed non-reproducibility in diffraction properties of protein crystals. Using flow cells with a constant supply of fresh protein may help to overcome this difficulty. Separating the nucleation and growth phases is another alternative (Chayen, 2005). This can be straightforwardly done by seeding procedures (see Section 4.1.4.4.).

4.1.5.4. Crystal perfection

The ultimate objective of structural biologists is to analyse crystals of high perfection, in other words, with a minimum of defects, disorder, impurity incorporation and internal stress. Such imperfections can be visualized using laser confocal microscopy combined with differential interference contrast microscopy (Iimura *et al.*, 2005; Sazaki *et al.*, 2005). They can also be evaluated by the resolution limit of diffraction, which expresses the average disorder of the molecules in the crystal lattice. Wilson plots provide good illustrations of diffraction quality for protein crystals. Other sources of disorder, such as the mosaic structure of the crystal, may strongly influence the quality of the diffraction data. They are responsible for increases in the diffuse background scatter and a broadening of diffraction intensities. These defects are difficult to monitor with precision, and dedicated techniques and instruments are required for accurate analysis.

Mosaicity can be defined experimentally by X-ray rocking width measurements. An overall diagnostic of crystal quality can be obtained by X-ray diffraction topography. Both techniques have been refined with lysozyme as a test case and were used for comparative analysis of crystals grown under different conditions, both on earth and in microgravity. For lysozyme and thaumatin, improvement of the mosaicity, as revealed by decreased rocking widths measured with synchrotron radiation, was observed for the microgravity-grown crystals (Snell *et al.*, 1995; Ng, Lorber *et al.*, 1997; Lorber, Sauter, Robert *et al.*, 1999).

An illustration of mosaic block character in a lysozyme crystal was provided by X-ray topography (Fourme *et al.*, 1995). Comparison of earth- and microgravity-grown lysozyme crystals showed a high density of defects in the earth control crystals, while in the microgravity case, several discrete regions were visible (Stojanoff *et al.*, 1996). X-ray topographs have also been used to compare crystal polymorphs (Izumi *et al.*, 1996), to monitor temperature-controlled growth of tetragonal lysozyme crystals (Stojanoff *et al.*, 1997), to study the effects of solution variations during growth on crystal perfection (Dobrianov *et al.*, 1998; Otálora *et al.*, 1999), to compare crystals grown in solution and in agarose gel (Lorber, Sauter, Ng *et al.*, 1999), and to map defects in the bulk of protein crystals (Hu *et al.*, 2001).



Preparation of target macromolecules
Cloning, expression, purification, biological activity assay, assessment of purity and structural homogeneity
Search for crystallization conditions
Trial-and-error search using sparse matrix screening kits, rational DLS-guided diagnostic, seeding
Design of modified macromolecules
Optimization of crystal growth conditions
Establishment of phase diagrams, control of supersaturation, crystallization in diffusive media, addition of ligands
Characterization of crystal properties
Biochemical and crystallographic analyses, microscopy, X-ray topography
Determination of 3D structures
Analysis of macromolecule structure, function and evolution, analysis of crystal packing

Figure 4.1.6.1

From the target molecule to its three-dimensional structure: a flowchart for a structure detemination. The figure illustrates the different steps the crystal grower will go through to access three-dimensional information. Ideally, the trajectory will be linear, crystallization remaining the major bottleneck in the whole process. If one gets stuck at any stage, the difficulties can often be circumvented by modifying the target molecule, either genetically or (bio)chemically, by improving its purity/homogeneity, or by adding ligands to stabilize its structure.

4.1.6. How to crystallize a new macromolecule: the structural biology view

Fig. 4.1.6.1 schematizes the progress of structural biology projects and highlights the pivotal role of the crystallization step. Despite tremendous progress in macromolecule and crystal preparation, crystallization remains the most serious bottleneck. Various strategies have been proposed to overcome the difficulty (*e.g.* D'Arcy, 1994; Ducruix & Giegé, 1999; Kundrot, 2004; McPherson, 2004; DeLucas *et al.*, 2005; Pusey *et al.*, 2005; Hughes & Ng, 2007; Li *et al.*, 2007; Chayen & Saridakis, 2008). The choice is largely dependent on the type of project [functional biology with well defined protein(s) or structural genomics with large ensembles of known and unknown proteins] and thus on non-exclusive rational, incomplete factorial screening, or empirical approaches.

4.1.6.1. How to start and how to choose what screening kits to start with

In practice, the very first questions posed when one begins to think about crystallization assays are: (i) which crystallization kit to start with, (ii) what to do if no crystals grow and (iii) what happens when one gets crystals. The answer to the first question is in fact simplest. One should start with a screen that does not unreasonably tax the supply of protein but which explores the widest volume of crystallization space, *i.e.* samples the largest number of crystallants and crystallant concentrations over the largest range of pH. There are many kits on the market using 96-sample trials that accomplish this well. If protein is severely limited, then there are 48-sample kits that do the job satisfactorily. In case of no success one should examine the resulting pattern of precipitates, phase separations, clear drops and assorted odd accumulations, and try to divine what might be the best option to try next. Good advice is to check how others have crystallized similar proteins and to try complexes of the protein with its physiological ligands and effectors.

If, on the other hand, one is fortunate and the first kit does indeed yield crystals, but perhaps of insufficient size or quality, or of troubling morphology, then crystallization must be optimized to get better ones. One should also check whether it is really the macromolecule that crystallized and not a ligand or any component of the crystallization mixture. Optimization means varying the chemical and physical parameters of the reagent mix that yielded the crystals and searching the crystallization parameter space by small increments away from the starting point. There is still a component of art and mystery in science, and this is one instance where its appreciation is paramount.

As a practical example, one can consider the 'Silver bullet' concept, which employs a limited set of fundamental crystallization conditions combined with a broad screen of potentially useful small-molecule additives (McPherson & Cudney, 2006), with the hypothesis that some of them might establish intermolecular noncovalent cross-links (Larson *et al.*, 2008). In the 'Uppsala' concept, a crystallization project entails two distinct steps: screening and optimization. The aim of the initial phase is to screen the parameters affecting crystallization as broadly as possible. If promising conditions are found, these are optimized with other protocols including grid and additive screens, seeding, and manipulation of drop kinetics (Bergfors, 2007).

4.1.6.2. Rules and general principles

Rules for sample preparation. The first concern is to obtain a macromolecular sample of the highest quality, second to collate all biochemical and biophysical information characterizing the macromolecule in order to design the best crystallization strategy, and finally, to establish precise protocols that ensure reproducibility of experiments. Solubility screening is an important issue and can be automated (Listwan *et al.*, 2009). Important as well is to clean and sterilize by filtration (over 0.22 µm porosity membranes, or even 0.10 µm) all solutions in contact with pure proteins, to remove dust and other solid particles, and to avoid contamination by microbes (Chayen, 2009). Inclusion of sodium azide in crystallizing solutions may discourage invasive bacteria and fungi. In vapour-diffusion assays, placing a small grain of thymol in the reservoir can prevent contamination. Thymol, however, can occasionally have specific effects on crystal growth (Chayen *et al.*, 1989) and thus may serve as an additive in screenings as well.

The preparation of solutions for crystallization experiments should follow some common rules. Stocks should be prepared with chemicals of the purest grade dissolved in double-distilled water, filtered through 0.22 µm membranes and ultracentrifuged (1 h at 100 000*g*) to remove aggregates. The chemical nature of the buffer is an important parameter, and the pH of buffers, which must be strictly controlled, is often temperature dependent, especially that of Tris buffers. Commercial PEG may contain ionic contaminants (Jurnak, 1986), or contaminants derived from peroxidation, and thus repurification is recommended (Ray & Puvathingal, 1985).

Mother liquors are defined as the solutions that contain all compounds (buffer, crystallant *etc.*) at the final concentration for crystallization, except the protein (to avoid dissolution of the crystals when transferred to a fresh mother liquor, soluble protein should be present). Samples of proteins often contain quantities of salt of unknown composition, and it is therefore wise to dialyse new batches against well characterized buffers. Whatever the crystallization method used, it almost always requires a high concentration of protein. This may imply concentration steps using devices operating under nitrogen pressure, by centrifugation or by lyophilization (note that lyophilization may denature proteins and that non-volatile salts will accumulate). Dialysis against high-molecular-weight PEG may also be used. During concentration, the pH and ionic strength may vary and, if not kept at the appropriate values, denaturation of samples may occur.

How to use phase diagrams and favour reproducibility. Crystallization requires bringing the protein to a supersaturated state that favours nucleation. Use of phase diagrams may be important for that purpose (Haas & Drenth, 1999; Sauter, Lorber *et al.*, 1999; Asherie, 2004; Lorber & Witz, 2008). If solubilities or phase diagrams are unavailable, it is nevertheless important to understand the correlation between solubility and the way supersaturation is reached in the different crystallization methods (Fig. 4.1.3.1). In dialysis, the protein concentration remains constant during equilibration. The initial concentration of the crystallant in the exterior solution leaves the macromolecule in an undersaturated state. With increasing concentration of this agent in the exterior solution, a state of supersaturation can be attained, leading to crystallization or precipitation. In a vapour-diffusion experiment, where the concentration of crystallant in the reservoir exceeds that in the drop, the protein will begin to concentrate from an undersaturated to a supersaturated state, with both protein and crystallant concentrations increasing. Crystals appear in the labile region. For crystals that appear first, the trajectory of equilibration is complex and the remaining concentration of protein in solution will converge towards a point located on the solubility curve. In batch crystallization using a closed vessel, three situations can occur: if the concentration of the protein is undersaturated, crystallization never occurs (unless another parameter such as temperature is varied); if it belongs to the supersaturated region between solubility and precipitation curves, crystals can grow until the remaining concentration of the protein in solution equals its solubility; if supersaturation is too high, the protein precipitates immediately, although in some cases crystals can grow from precipitates by Ostwald ripening (Ng *et al.*, 1996; Lorber & Witz, 2008). Altogether, the crystal habits (*e.g.* Sauter, Lorber *et al.*, 1999; Zhu *et al.*, 2001) and the underlying growth mechanisms (Fig. 4.1.5.1) are dependent on the region in the phase diagram where nucleation occurred and on the equilibration trajectories (Figs. 4.1.1.1 and 4.1.3.1).

Reproducibility should be a strategic concern (Newman *et al.*, 2007), but is often not reached despite the efforts of investigators to work with protein and crystallant solutions of identical chemical composition. Besides the many reasons that could explain this situation, the effect of the mixing protocol of the different components constituting a crystallization drop on the output of the experiment is often overlooked. Since mixing is not instantaneous, it will generate local supersaturation maxima and minima that can affect the crystallization process. Thus, when seeking reproducibility, active mixing of the crystallization drops is recommended, which is easy to perform when working manually but not trivial in automated procedures (Howard *et al.*, 2009).

4.1.6.3. Database mining and statistics

With the number of protein structures solved by X-ray crystallography now approaching 100 000, substantial databases of successful crystallization conditions and procedures have been developed (*e.g.* Peat *et al.*, 2005; Li *et al.*, 2007; Tung & Gallagher, 2009). From these it might be expected that some predictive insight would be obtained regarding the most probable crystallization conditions for proteins in general (*e.g.* Kimber *et al.*, 2003), and for specific families of proteins sharing common physical, chemical or functional properties such as aminoacyl-tRNA synthetases (Giegé *et al.*, 2008). However, the problem is that each protein remains an individual endowed with its own eccentricities, even within a family, and often these dramatically alter its crystallization behaviour. In addition, proteins in general may be exquisitely sensitive to only minor modifications to their properties, further complicating their rational classification in terms of crystal growth.

Nonetheless, statistical analyses are now being widely applied to the expanding databases and some results, both interesting and useful, are beginning to emerge. For example, reduced sets of the most favourable crystallization conditions have been proposed by several groups of investigators based on past successes. These may be useful because they reduce the number of crystallization trials in cases where either the amount of protein is limited or a very large number of constructs are to be screened. Favoured reagents and, particularly, useful additives have been identified by such analyses. Correlations have been sought between the physical or chemical properties of specific proteins and their manner of crystallization, such as between pI and crystallization pH, but this has had only limited success. A promising method generates relatively accurate predictions from protein composition and collocation of amino acids, pI and hydrophobicity deduced from sequence data, and number of solved structures of similar sequences (Mizianty & Kurgan, 2009). Interestingly, data mining of biophysical properties that control protein crystallization led to the conclusion that crystallization propensity depends primarily on the prevalence of well ordered surface epitopes capable of mediating interprotein interactions rather than on the overall thermodynamic stability of the proteins (Price *et al.*, 2009).

4.1.6.4. Strategic concerns: a summary

Homogeneity and stability. Perhaps the most important property of a system to be crystallized is its purity. Crystallization presupposes that identical units are available for incorporation into a periodic lattice. If crystallization fails, reconsidering purification protocols often helps achieve success. No homogeneous molecular population can remain so if its members alter their form, folding or association state. Hence, it is crucial that proteins in solution not be allowed to denature, aggregate or undergo conformational changes.

Solubility. Before a molecule can be crystallized, it must be solubilized. This means creation of monodisperse solutions free of aggregates and molecular clusters. Solubility and crystallizability strongly depend on substances (organic solvents and PEGs) that reduce the ionic strength of the solution (Papanikolau & Kokkinidis, 1997).

Supersaturation and nucleation. Crystals grow from systems displaced from equilibrium so that restoration requires formation of the solid state. Thus, the first task is to find ways to alter properties of the crystallizing solutions, such as by pH or temperature change, and to create supersaturated states. The number, size and quality of crystals depend on the mechanisms and rates of nuclei formation. For diffraction work in crystallization, one must seek to induce limited nucleation by adjustment of the physical and chemical properties of the system.

Association and variety. In forming crystals, molecules organize themselves through self-association to produce periodically repeating, three-dimensional arrays. Thus, it is necessary to facilitate positive molecular interactions while avoiding formation of precipitate, unspecific aggregates or phase separation. Proteins may crystallize under a wide spectrum of conditions and form many polymorphs. Thus, one should explore as many opportunities for crystallization as possible and explore the widest spectrum of biochemical, chemical and physical parameters.

Control and perfection. The ultimate value of any crystal is dependent on its perfection. Perturbations of the mother liquor are, in general, deleterious. Thus, crystallizing systems have to be maintained at an optimal state, without fluctuations or shock, until the crystals have matured. Crystallization conditions should be such as to favour crystal perfection, to minimize defects and high mosaicity of the growing crystals, and to minimize internal stress and incorporation of impurities. Predictions from crystal-growth theories may help to define such conditions (Chernov, 2003).

Impurities and preservation. Impurities can contribute to a failure to nucleate or to grow quality crystals. Thus, one must discourage their presence in the mother liquor and their incorporation into the lattice. Protein crystals may degrade and lose diffraction quality upon ageing. Thus, once grown, crystals may be stabilized by temperature change, addition of more crystallant or by some other suitable alteration in the mother liquor.

Rational design versus *automation*. When an investigation is focused on a single crystallographic objective, the structure solution of a specific protein or macromolecular complex, then it is wise to put as much time into headwork (thinking) as into handiwork (setting up crystallization samples). Examining and evaluating results, divining insights and setting new directions are certainly as important as actually dispensing samples into crystallization plates. There are, however, instances where it is more efficient to automate the process by which crystallization conditions are identified and optimized. This is true when there is not one, but many, real or potential targets.

4.1.7. The future of protein crystal growth

The fact that high-quality X-ray diffraction data can frequently be obtained from a single crystal of dimensions in the range of 20 to 50 μm has changed the objectives considerably from 40 years ago, when many crystals in the millimetre size range were required for a structure analysis. A consequence of this is that attention is turning increasingly from the systematic growth of large protein crystals (Bailey, 1942) to the nucleation and growth of any crystal. This direction has been further promoted by the development in the last 20 years of methods to use even the data from twinned or disordered crystals. One might be led to believe that the future of crystal growth is shrinking dramatically. Indeed, while smaller, fewer crystals are now the rule (with the exception of those required for neutron diffraction), this has not reduced the value of crystal perfection, nor the requirement that at least some sort of crystal be obtained. Thus, attention is now focused on nucleation, perhaps always the most problematic step in the crystallization process, and enhancing crystal perfection. These continue to remain formidable problems.

Furthermore, the objectives of crystallization, the entities to be crystallized, will continue to become more challenging. In addition to membrane proteins that pose difficult problems because of their solubility (see Chapter 4.2), interest has increasingly turned towards the solutions of the structures of RNA, glycoproteins (Chang *et al.*, 2007), lipoproteins, and larger protein or protein–nucleic acid complexes and assemblies. It is unlikely that crystals with unit cells much above 1200 Å can be solved with current X-ray technologies, but even those assemblies, such as large icosahedral viruses, that do yield crystals amenable to analysis are remarkably fragile in a mechanical sense, and the large unit-cell size requires that the crystals greatly exceed the small sizes of conventional protein crystals. Additional problems will arise from proteins conjugated with other entities of significant size such as lipids and oligosaccharides, which are often disordered, and with proteins that are unstructured, in whole or in part.

Finally, we have come to believe that the structure of a protein in the crystal is the same as the structure of the protein in solution. But when the protein has a spectrum of conformations in solution, as a consequence often of its function, then to visualize it in full one needs to see it in multiple crystal forms. Thus, it will be increasingly necessary to grow crystals not simply of the apo protein, but also of its possible ligand complexes, and possibly in several polymorphs. By studying the protein in a variety of crystal forms, its conformational variety may be appreciated and its dynamic range delineated.

Chapter 4.2. Crystallization of membrane proteins

H. Michel

4.2.1. Introduction

At the time of writing, the Protein Data Bank contains more than 8000 entries of protein structures. These belong to roughly 1200 sequence-unrelated protein families, which can be classified into ~350 different folds (Gerstein, 1998). However, all known membrane-protein structures belong to one of a dozen membrane-protein families. Membrane proteins for which the structures have been determined are bacterial photosynthetic reaction centres, porins and other β-strand barrel-forming proteins from the outer membrane of Gram-negative bacteria, bacterial light-harvesting complexes, bacterial and mitochondrial cytochrome *c* oxidase, the cytochrome bc_1 complex from mammalian mitochondria, two cyclooxygenases, squalene cyclase, and two bacterial channel proteins. These structures have been determined by X-ray crystallography. In addition, the structures of two membrane proteins, namely that of bacteriorhodopsin and that of the plant light-harvesting complex II, have been solved by electron crystallography (see Chapter 19.6). Table 4.2.1.1 provides a list of the membrane proteins with known structures. It also contains the key references for the structure descriptions and the crystallization conditions.

It is known from genome sequencing projects that 20–35% of all proteins contain at least one transmembrane segment (Gerstein, 1998), as deduced from the occurrence of stretches of hydrophobic amino acids that are long enough to span the membrane in a helical manner. These numbers may be an underestimate, because β-strand-rich membrane proteins like the porins, or membrane proteins which are only inserted into the membrane, but do not span it ('monotopic membrane proteins'), like cyclooxygenases (prostaglandin-H synthases), cannot be recognized as being membrane proteins by inspecting their amino-acid sequences.

Why do we know so few membrane-protein structures? The first reason is the lack of sufficient amounts of biochemically well characterized, homogeneous and stable membrane-protein preparations. This is especially true for eukaryotic receptors and transporters (we do not know the structures of any of these proteins). For these, a major problem is the lack of efficient expression systems for heterologous membrane-protein production. It is therefore not surprising that most membrane proteins with known structure are either involved in photosynthesis or bioenergetics (they are relatively abundant), or originate from bacterial outer membranes (they are exceptionally stable and can be overproduced). Second, membrane proteins are integrated into membranes. They have two polar surface regions on opposite sides (where they are in contact with the aqueous phases and the polar head groups of the membrane lipids) which are separated by a hydrophobic belt. The latter is in contact with the alkyl chains of the lipids. As a result of this amphipathic nature of their surface, membrane proteins are not soluble in either aqueous or organic solvents. To isolate membrane proteins one first has to prepare the membranes, and then solubilize the membrane proteins by adding an excess of detergent. Detergents consist of a polar or charged head group and a hydrophobic tail. Above a certain concentration, the so-called *critical micellar concentration* (CMC), detergents form *micelles* by association of their hydrophobic tails. These micelles take up lipids. Detergents also bind to the hydrophobic surface of membrane proteins with their hydrophobic tails and form a ring-like detergent micelle surrounding the membrane protein, thus shielding the hydrophobic belt-like surface of the membrane protein from contact with water. This is the reason for their ability to solubilize membrane proteins, although with detergents with large polar head groups it is sometimes difficult to achieve a rapid and complete solubilization. The solubilizate, consisting of these mixed protein–detergent complexes as well as lipid-containing and pure detergent micelles, is then subjected to similar purification procedures as are soluble proteins. Of course, the presence of detergents complicates the purification procedures. The choice of the detergent is critical. The detergent micelles have to replace, and to mimic, the lipid bilayer as perfectly as possible, in order to maintain the stability and activity of the solubilized membrane protein. The solubilization of membrane proteins has been reviewed by Hjelmeland (1990) and the general properties of the detergents used has been reviewed by Neugebauer (1990).

4.2.2. Principles of membrane-protein crystallization

There are two principal types of membrane-protein crystals (Michel, 1983). First, one can think of forming two-dimensional crystals in the planes of the membrane and stacking these two-dimensional crystals in an ordered way with respect to up and down orientation, rotation and translation. This membrane-protein crystal type ('type I') is attractive, because it contains the membrane proteins in their native environment. It should even be possible to study lipid–protein interactions. Crystals of bacteriorhodopsin of this type have been obtained either upon slow removal of the detergent by dialysis at high ionic strength (Henderson & Shotton, 1980), or by a novel approach using lipidic bicontinuous cubic phases (Landau & Rosenbusch, 1996; Pebay-Peyroula *et al.*, 1997; see also below). Alternatively, one can try to crystallize the membrane protein with the detergents still bound in a micellar manner. These crystals are held together *via* polar interactions between the polar surfaces of the membrane proteins. The detergent plays a more passive, but still critical, role. Such 'type II' crystals look very much like crystals of soluble globular proteins. The same crystallization methods and equipment as for soluble globular proteins (see Chapter 4.1) can be used. However, the use of hanging drops is sometimes difficult, because the presence of detergents leads to a lower surface tension of the protein solution. Intermediate forms between type I and type II crystals are feasible, *e.g.* by fusion of detergent micelles.

The use of detergent concentrations just above the CMC of the respective detergent is recommended in order to prevent complications caused by pure detergent micelles. Unfortunately, the CMC is not constant. Normally, the CMC provided by the vendor has been determined in water at room temperature. A compilation of potentially useful detergents, their CMCs and their molecular weights is presented in Table 4.2.2.1. The CMC is

Table 4.2.1.1

Compilation of membrane proteins with known structures, including crystallization conditions and key references for the structure determinations

This table is continuously updated and can be inspected at http://www.mpibp-frankfurt.mpg.de/michel/public/memprotstruct.html. The membrane proteins listed are divided into polytopic membrane proteins from inner membranes of bacteria and mitochondria (*a*), membrane proteins from the outer membrane of Gram-negative bacteria (*b*) and monotopic membrane proteins [(*c*); these are proteins that are only inserted into the membrane, but do not span it]. Within parts (*a*), (*b*) and (*c*) the membrane proteins are listed in chronological order of structure determination.

(*a*) Polytopic membrane proteins from inner membranes of bacteria and mitochondria.

Membrane protein	Crystallization conditions (detergent/additive/precipitating agent)	Key references (and pdb reference code, if available)
Photosynthetic reaction centre		
from *Rhodopseudomonas viridis*	*N*,*N*-Dimethyldodecylamine-*N*-oxide/heptane-1,2,3-triol/ammonium sulfate	[1], [2] (1PRC), [3], [4] (2PRC, 3PRC, 4PRC, 5PRC, 6PRC, 7PRC)
from *Rhodobacter sphaeroides*	*N*,*N*-Dimethyldodecylamine-*N*-oxide/heptane-1,2,3-triol/polyethylene glycol 4000	[5] (4RCR)
	Octyl-β-D-glucopyranoside/polyethylene glycol 4000	[6] (2RCR)
	N,*N*-Dimethyldodecylamine-*N*-oxide/heptane-1,2,3-triol, dioxane/potassium phosphate	[7] (1PCR)
	Octyl-β-D-glucopyranoside/benzamidine, heptane-1,2,3-triol/polyethylene glycol 4000	[8] (1AIG, 1AIJ)
Bacteriorhodopsin		
from *Halobacterium salinarium*	(Electron crystallography using naturally occuring two-dimensional crystals)	[9] (1BRD), [10] (2BRD), [11] (1AT9)
	(Type I crystal grown in lipidic cubic phases)	[12] (1AP9), [13] (1BRX)
	Octyl-β-D-glucopyranoside/benzamidine/sodium phosphate (epitaxic growth on benzamidine crystals)	[14] (1BRR)
Light-harvesting complex II		
from pea chloroplasts	(Electron crystallography of two-dimensional crystals prepared from Triton X100 solubilized material)	[15]
Light-harvesting complex 2		
from *Rhodopseudomonas acidophila*	Octyl-β-D-glucopyranoside/benzamidine/phosphate	[16] (1KZU)
from *Rhodospirillum molischianum*	*N*,*N*-dimethylundecylamine-*N*-oxide/heptane-1,2,3-triol/ammonium sulfate	[17] (1LGH)
Cytochrome *c* oxidase		
from *Paracoccus denitrificans*,		
four-subunit enzyme complexed with antibody Fv fragment	Dodecyl-β-D-maltoside/polyethylene glycol monomethylether 2000	[18]
two-subunit enzyme complexed with antibody Fv fragment	Undecyl-β-D-maltoside/polyethylene glycol monomethylether 2000	[19] (1AR1)
from bovine heart mitochondria	Decyl-β-D-maltoside with some residual cholate/polyethylene glycol 4000	[20], [21] (1OCC), [22] (2OCC, 1OCR)
Cytochrome bc_1 complex		
from bovine heart mitochondria	Decanoyl-*N*-methylglucamide or diheptanoyl phosphatidyl choline/polyethylene glycol 4000	[23] (1QRC), [24]
	Octyl-β-D-glucopyranoside/polyethylene glycol 4000	[25]
	Pure dodecyl-β-D-maltoside or mixture with methyl-6-*O*-(*N*-heptylcarbamoyl)-α-D-glucopyranoside/polyethylene glycol 4000	[26]
from chicken heart mitochondria	Octyl-β-D-glucopyranoside/polyethylene glycol 4000	[25] (1BCC, 3BCC)
Potassium channel		
from *Streptomyces lividans*	*N*,*N*-Dimethyldodecylamine/polyethylene glycol 400	[27] (1BL8)

from *Mycobacterium tuberculosis*	Dodecyl-β-D-maltoside/triethylene glycol	[28]

generally lower at high ionic strength and at high temperatures. The presence of glycerol and similar compounds, as well as that of chaotropic agents (Midura & Yanagishita, 1995), also influences (decreases) the CMC.

4.2.3. General properties of detergents relevant to membrane-protein crystallization

The presence of detergents sometimes causes problems. The monomeric detergent itself can crystallize, *e.g.* dodecyl-β-D-maltoside at 4 °C in the presence of polyethylene glycol. The detergent crystals might be mistaken for protein crystals. Detergent micelles possess attractive interactions (see Zulauf, 1991). Upon addition of salts or polyethylene glycol, or upon temperature changes, a phase separation may be observed: owing to an increase in these attractive interactions, the detergent micelles 'precipitate', forming a viscous detergent-rich phase and a detergent-depleted aqueous phase. The membrane proteins are found exclusively in the viscous phase and crystals – if formed – are difficult to handle. Some detergents, *e.g.* those with polyoxyethylene head groups, undergo a phase separation at higher temperatures. This phenomenon has been used to separate

Table 4.2.1.1 (continued)

(*b*) Membrane proteins from the outer membrane of Gram-negative bacteria and related proteins.

solubilized membrane proteins, which are found in the detergent-rich phase, from the water-soluble proteins. The latter are concentrated in the detergent-depleted phase (Bordier, 1981). Other detergents, *e.g.* octyl-β-D-glucopyranoside, show this phase separation at lower temperatures. Therefore, if phase separation causes problems, a change of the crystallization temperature may help.

The polar head groups of the detergents influence their usage in many ways. One would like to have a small polar head group, because the head group 'covers' the part of the protein's polar surface that is adjacent to the hydrophobic surface belt. The bigger the head group the more of the polar surface is covered and unavailable for the polar interactions needed to form the crystal lattice. Unfortunately, detergents with small polar head groups are rather denaturing. Detergents with charged head groups cannot be used, but detergents with zwitterionic head groups, *e.g.* sulfobetaines, can be tried with more stable proteins. The head group of a very successful detergent, *N*,*N*-dimethyldodecylamine-*N*-oxide, is of zwitterionic nature. I estimate that it can only be used with about 20% of all membrane proteins. Detergents with sugar residues as head groups have been used successfully. Octyl-β-D-glucopyranoside also tends to be denaturing. The lifetime of many membrane proteins can be prolonged by a factor of three by the use of nonyl-β-D-glucopyranoside instead of the shorter homologue. Such behaviour is observed within each series of homologous detergents; an increase in the alkyl chain by one methylene group leads to an increase in stability by a factor of three, an increase by two methylene groups leads to an increase in stability by a factor of about ten. Unfortunately, decyl-β-D-glucopyranoside is too insoluble to be used as detergent. For less stable membrane proteins, alkylmaltoside detergents or alkanoylsucrose deter-

Table 4.2.2.1

Potentially useful detergents for membrane-protein crystallizations with molecular weights and CMCs [in water, from Michel (1991) or as provided by the vendor]

gents have to be tried. There is one special problem when using alkyl-β-D-glucopyranosides or alkyl-β-D-maltosides as detergents: the commercially available detergents are often 'contaminated' with the α-anomers in varying, sometimes substantial, concentrations. The α-anomers are much less soluble, and appear to prevent crystallization. In the case of photosystem I from a thermophilic cyanobacterium, it has been reported that for a 2% α-anomer content in dodecyl-β-D-maltoside preparations no crystals can be obtained, with a 0.5–2% content the diffraction of the crystals is anisotropic with a reduction in resolution to 5–6 Å, whereas diffraction to better than 3.5 Å resolution in all directions is observed when the content of the α-anomer is below 0.1% (Fromme & Witt, 1998). The percentage of α-anomer can be determined using NMR spectroscopy or high-performance liquid chromatography. During ageing of detergent solutions, a conversion from the β-anomer to the α-anomer is expected. Therefore, ageing of detergent solutions has to be prevented.

The detergents that have been successfully used to crystallize membrane proteins can also be found in Table 4.2.1.1. The possibilities for developing new detergents for membrane-protein crystallization have not been exhausted. There is a need for new detergents, *e.g.* detergents with head groups with sizes between glucose and maltose are still missing!

It has been observed that crystals of the photosynthetic reaction centre from the purple bacterium *Rhodopseudomonas viridis* could be obtained when *N*,*N*-dimethyldodecylamine-*N*-oxide is used as detergent, but not when *N*,*N*-dimethyldecylamine-*N*-oxide is used. Even crystals formed with the dodecyl homologue lost their order when soaked in a buffer containing the decyl homologue. These observations were found to have an obvious explanation when the location of the detergent molecules bound to the protein was determined using neutron crystallography (Roth *et al.*, 1989); the detergent molecules surrounding neighbouring photosynthetic reaction centres in the crystal lattice are in contact. It is likely that attractive interactions between neighbouring protein-bound detergent micelles contribute to the stability of the crystal lattice. Particularly striking (see Table 4.2.3.1) is the dependence of the crystal quality on the alkyl-chain length in the case of the two-subunit cytochrome *c* oxidase from the soil bacterium *Paracoccus denitrificans.* Well ordered crystals were obtained with undecyl-β-D-maltoside, but not with the decyl and dodecyl homologues. Table 4.2.3.1 also lists the names of important vendors of detergents.

4.2.4. The 'small amphiphile concept'

From the arguments and observations presented above, it is evident that the size and shape of the detergent micelle are very important in membrane-protein crystallization. Detergent micelles can be made smaller (and their curvatures changed) when small amphiphilic molecules like heptane-1,2,3-triol are

Table 4.2.3.1

Summary of the results of attempts to crystallize the two-subunit cytochrome *c* oxidase from the soil bacterium *Paracoccus denitrificans* using different detergents (after Ostermeier *et al.*, 1997)

The resolutions of the crystals obtained are given in parentheses. Abbreviations: C_{12}: dodecyl; C_{11}: undecyl; C_{10}: decyl; C_9: nonyl; CYMAL-6: (cyclohexyl)hexyl-β-D-maltoside; CYMAL-5: (cyclohexyl)pentyl-β-D-maltoside. x in E_x is the number of oxyethylene units in the alkylpolyoxyethylene detergents. Suppliers: A: Anatrace (Maumee, OH); B: Biomol; C: Calbiochem; F: Fluka.

Detergent	Supplier	Crystals?
C_{12}-β-D-maltoside	B	Yes (8 Å)
C_{11}-β-D-maltoside	B	Yes (2.5 Å)
C_{10}-β-D-maltoside	B	No
CYMAL-6	A	Yes (2.6 Å)
CYMAL-5	A	No
Dodecylsucrose	C	No
Decylsucrose	C	No
C_9-β-D-glucoside	C	No
$C_{12}E_8$	F	Yes (> 8 Å)
$C_{12}E_6$	F	No
$C_{12}E_5$	F	No
$C_{10}E_6$	F	No
$C_{10}E_5$	F	No

added (Timmins *et al.*, 1991; Gast *et al.*, 1994). These compounds form mixed micelles with detergents. When 10% (*w*/*v*) heptane-1,2,3-triol is added to 1% solutions of *N*,*N*-dimethyldodecylamine-*N*-oxide in water, the number of detergent molecules per micelle decreases from 69 to 34, ~23 heptane-1,2,3-triol molecules are incorporated and the radius of the micelle is reduced from 20.9 to 16.9 Å (Timmins *et al.*, 1994). This so-called 'small amphiphile concept' has been used successfully to crystallize bacterial photosynthetic reaction centres (Michel, 1982, 1983; Buchanan *et al.*, 1993), bacterial light-harvesting complexes (Michel, 1991; Koepke *et al.*, 1996) and other membrane proteins (see Table 4.2.1.1). The light-harvesting complexes from the purple bacterium *Rhodospirillum molischianum* yield an astonishing number of different crystal forms, but only one diffracts to high resolution. A large amount of heptane-1,2,3-triol had to be added to obtain this crystal form. As a result, heptane-1,2,3-triol itself reached supersaturation during crystallization of the protein. Normally, the protein crystallizes first and heptane-1,2,3-triol later. When heptane-1,2,3-triol crystals form, the protein crystals crack and eventually redissolve. A likely explanation is that the concentration of solubilized heptane-1,2,3-triol is reduced when it forms crystals and the mixed detergent–heptane-1,2,3-triol micelles lose heptane-1,2,3-triol and take up detergent molecules from solution. The micelles expand and the crystals crack. This behaviour caused severe problems when searching for heavy-atom derivatives. Small amphiphiles work well with the *N*,*N*-dimethylalkylamine-*N*-oxides and alkylglucopyranosides as detergents, but not with alkylmaltosides. The most successful small amphiphiles are heptane-1,2,3-triol and benzamidine.

4.2.5. Membrane-protein crystallization with the help of antibody Fv fragments

The number of detergents that can be tried is limited for rather unstable membrane proteins. For instance, the four-subunit cytochrome *c* oxidase from *P. denitrificans* is sufficiently stable only with dodecyl-β-D-maltoside as detergent. When other detergents are employed, subunits III and IV and some lipids are removed from subunits I and II. These lipids might contribute to the binding of the protein subunits III and IV to the central subunits I and II. Therefore, the size of the detergent micelles can not be varied by using different detergents. In order to obtain crystals, the size of the extramembraneous part of this important enzyme was enlarged by the binding of Fv fragments of monoclonal antibodies. For this purpose, monoclonal antibodies against the four-subunit cytochrome *c* oxidase were generated using the classical hybridoma technique. Then hybridoma cell lines producing conformation-specific antibodies were selected (such antibodies react positively in enzyme-linked immunosorbent assays, but negatively in Western blot assays). The cDNA strands coding for the respective VL and VH genes were cloned and expressed in *Escherichia coli.* Binding of conformation-specific antibody fragments can be expected to lead to a more homogeneous protein preparation. The first Fv fragment worked, and well ordered crystals of the four-subunit and two-subunit cytochrome *c* oxidases were obtained (Ostermeier *et al.*, 1995, 1997). As an important additional advantage of this approach, an affinity tag can be fused to the recombinant antibody Fv fragment and used for efficient isolation. The affinity tag can then be used to purify the complex of antibody fragment and membrane protein rapidly and with a high yield (Kleymann *et al.*, 1995). Because Fv fragment cocrystallization also worked with the yeast cytochrome bc_1 complex, again with the first and only conformation-specific antibody Fv fragment tried (Hunte *et al.*, 2000), we are rather confident about this method for the future. The usefulness of single-chain Fv fragments, which can be obtained by the phage-display technique, has not been investigated, because the linker region joining the VL and VH chains must be expected to be flexible. Such flexibility would induce inhomogeneity and reduce the chance of obtaining crystals.

4.2.6. Membrane-protein crystallization using cubic bicontinuous lipidic phases

Landau & Rosenbusch (1996) introduced the use of bicontinuous cubic phases of lipids for membrane-protein crystallization. In such phases, the lipid forms a single, curved, continuous three-dimensional bilayer [see Lindblom & Rilfors (1989) for a review]. One can incorporate membrane proteins into such a bilayer, as demonstrated with octyl-β-D-glucopyranoside-solubilized monomeric bacteriorhodopsin. The three-dimensional bilayer network serves as a matrix for crystallization. The membrane protein can diffuse through the bilayer, but is also able to establish polar contacts in the third dimension. Landau & Rosenbusch demonstrated that bacteriorhodopsin forms small, well ordered three-dimensional crystals. The X-ray data indicate that the same two-dimensional crystals are present as formed by bacteriorhodopsin in its native environment (the purple membrane). These membranes are now stacked in the third dimension in a well ordered manner. Therefore, these crystals belong to type I.

The method has the conceptual problem that the growing three-dimensional crystal has to disrupt and displace the cubic lipidic phase. Nevertheless, it is hoped that this method can also be used for membrane proteins that do not have a strong tendency to form two-dimensional crystals spontaneously. In particular, this method appears to be the only chance for crystallizing those membrane proteins that are unstable in the absence of added lipids.

4.2.7. General recommendations

When trying to crystallize a membrane protein the first, and most important, task is to obtain a pure, stable and homogeneous preparation of the membrane protein under investigation.

Unfortunately, general methods for producing substantial amounts of membrane proteins using heterologous expression systems in a native membrane environment do not exist, nor is refolding of membrane proteins from inclusion bodies well established. Once a pure and homogeneous preparation of a membrane protein has been obtained, its stability in various detergents has to be investigated at different pH values. Frequently, a sharp optimum pH for stability is observed with detergents of shorter alkyl-chain length. In crystallization attempts, the usual parameters (nature of the precipitant, buffer, pH, addition of inhibitors and/or substrates, see Chapter 4.1) should be varied. The most important variable, however, is the detergent. Detergents can be exchanged most conveniently by binding the membrane protein to column materials (*e.g.* ion-exchange resins, hydroxyapatite, affinity matrices), washing with a buffer containing the new detergent at concentrations above the CMC under non-eluting conditions, and then eluting the bound membrane protein with a buffer containing the new detergent. The completeness of the detergent exchange should be checked. For this purpose, the use of ^{14}C- or ^{3}H-labelled detergents is recommended. Washing with about 20 column volumes is frequently required for a complete detergent exchange. It is more difficult to exchange a detergent with a low CMC (this means long alkyl chains) against a detergent with a high CMC (shorter alkyl chains). The detergent can often be exchanged during a final step in the purification. Less satisfying methods for detergent exchange are molecular-sieve chromatography, ultracentrifugation or repeated ultrafiltration and dilution. If the amount of membrane protein is limited, it is advisable to restrict the usual parameters to a set of, *e.g.*, 48 standard combinations with respect to precipitating agent, pH, buffer *etc.*, but to try *all* available detergents. If crystals of insufficient quality or size are obtained, trying the antibody Fv fragment approach is highly recommended. Alternatives are to use a different source (species) for the membrane protein under investigation, or to remove flexible parts of the membrane protein by proteolytic digestion. I am convinced that 50% of all membrane proteins will yield well ordered, three-dimensional crystals within five years, once the problem of obtaining a pure, stable and homogeneous preparation has been solved.

Chapter 4.3. Application of protein engineering to enhance crystallizability and improve crystal properties

Z. S. Derewenda

4.3.1. Introduction

Following the dawn of recombinant technology brought about by the groundbreaking overexpression of synthetic genes coding for insulin and somatostatin in *Escherichia coli* (Goeddel *et al.*, 1979; Itakura *et al.*, 1977) and the subsequent discovery of the polymerase chain reaction (PCR; Mullis *et al.*, 1986; Saiki *et al.*, 1985, 1988), macromolecular crystallography was freed of its long-standing dependence on purified native protein samples for crystallization. Heterologous expression made it possible to generate samples of proteins and complexes that are found in only small or trace amounts in living cells and to engineer large and unstable proteins so that isolated domains or modified forms can be made available for crystallization. At the same time, the effort required for protein purification was dramatically reduced by the use of fusion proteins and affinity tags (Brewer *et al.*, 1991; Sassenfeld, 1990; Malhotra, 2009). As a consequence, the overwhelming majority of samples used today for crystallization are recombinantly derived proteins. However, even though material for crystallization is more easily available, the preparation of single, well diffracting crystals of the target macromolecule is still a time-consuming challenge.

Historically, two complementary approaches to protein crystallization were developed in parallel. Firstly, natural variations in the amino-acid sequences of homologues from different species were exploited to identify a target with suitable crystallization properties during the purification procedure (Kendrew *et al.*, 1954; Campbell *et al.*, 1972). The second approach was to extensively screen a specific target protein against a range of diverse precipitating agents, buffers and additives until the right conditions for crystallization were identified (Carter & Carter, 1979; Jancarik & Kim, 1991). These strategies remain the pillars of contemporary macromolecular crystallization. However, as the palette of molecular biology techniques expanded to include site-directed mutagenesis, ligation-independent cloning and other tools, it became possible to modify proteins with relative ease with the specific purpose of enhancing their propensity to crystallize or improving the diffraction quality of the resulting crystals. The early proof-of-principle of these capabilities was the crystallization of an engineered variant of human H-ferritin in which a single-site mutation, K86Q, was introduced to duplicate a crystal contact mediated by Cd^{2+} ions in the crystal structure of the homologous rat L-ferritin (Lawson *et al.*, 1991).

In this review, current progress in the methodologies of protein engineering used to enhance the crystallizability of targets that are recalcitrant to crystallization in their wild-type form is discussed. This burgeoning field is very broad and includes both general strategies that apply to a range of targets and many diverse approaches that only apply to specific proteins or protein families. Thus, owing to space limitations, the focus is on those techniques that have either been demonstrated to be of general utility or are at a point in their development to clearly have the potential to become widely used in the future. Understandably, only representative examples are provided.

4.3.2. Microscopic aspects of protein crystallization

Proteins are inherently dynamic entities, a property that greatly hinders their crystallizability. Not surprisingly, it has been estimated that even for the stable and relatively small single-domain prokaryotic proteins fewer than one in four will yield X-ray-quality crystals when using a routine screening process (Canaves *et al.*, 2004; Price *et al.*, 2009). In order to rationally modify proteins to enhance their crystallizability, it is first necessary to understand the physical properties that make most proteins resistant to crystallization.

Protein crystals are nucleated *ab initio* at supersaturation levels in the 200–1000% range (McPherson, 1982). Nucleation is believed to proceed *via* a two-step process: clusters of solute molecules form first and upon reaching critical size reorganize into three-dimensionally ordered nuclei (Georgalis *et al.*, 1997; Vekilov, 2004; Erdemir *et al.*, 2009). Subsequent transfer of protein molecules from solution onto the growing crystal surface is driven by relatively small negative changes in Gibbs free energy (ΔG°), from approximately -10 to $-100\,\mathrm{kJ\,mol^{-1}}$, at ambient temperature (Vekilov, 2003). Interestingly, enthalpy changes are generally negligible during crystallization (Yau *et al.*, 2000; Petsev *et al.*, 2001; Gliko *et al.*, 2005), so that entropic phenomena dominate (Vekilov *et al.*, 2002; Vekilov, 2003; Derewenda & Vekilov, 2006). The microscopic effects underlying the entropy changes, both favourable and unfavourable, involve the protein itself as well as the solvent. Protein packing, which results in an ordered three-dimensional lattice and loss of translational and rotational degrees of freedom, is unfavourable and produces an energy barrier in the 30–100 $\mathrm{kJ\,mol^{-1}}$ range at room temperature (Finkelstein & Janin, 1989; Tidor & Karplus, 1994). Similarly, incorporation into the growing crystal and ordering of any intrinsically unstructured elements, such as flexible termini or loops and side chains, at the point of crystal contacts further increases the entropic cost. However, the release of ordered solvent molecules from the surfaces involved in crystal contacts, which is estimated to be in the 25–150 $\mathrm{kJ\,mol^{-1}}$ range, may sufficiently compensate for these entropy losses and ultimately provide the driving force for crystal growth (Vekilov *et al.*, 2002; Vekilov, 2003).

Based on these considerations, it is evident that a protein must satisfy certain criteria in order to crystallize. Firstly, it must have a molecular surface that confers adequate solubility under initial conditions to reach the necessary supersaturation level for nucleation. Furthermore, it should have few, if any, intrinsically unstructured fragments such as extended N- or C-termini or long and solvent-exposed loops which may impede crystallization. Finally, the protein should have distinct ‘sticky’ patches on the surface with a structured layer of solvent molecules, allowing the ordering of nascent nuclei by mediating thermodynamically viable specific crystal contacts.

The notion that protein crystallization involves specific and anisotropic intermolecular interactions, as opposed to random contacts, is relatively new. Early analyses of intermolecular contacts in protein crystals concluded that crystallization is a

Copyright © 2012 International Union of Crystallography

stochastic process generated by mostly random contacts (Janin & Rodier, 1995; Janin, 1997; Carugo & Argos, 1997). However, more recent stringent statistical analyses using a larger database strongly suggested that crystal contacts are generated by anisotropic interactions that favour small hydrophobic residues and disfavour large polar side chains with high conformational entropy (Cieślik & Derewenda, 2009). This view is also supported by a large-scale comparison of the amino-acid sequences of crystallizable and noncrystallizable proteins, which established that crystallization propensity is negatively correlated with the prevalence of residues with high side-chain entropy (Price *et al.*, 2009). Finally, molecular-dynamics simulations of the intermolecular interactions of lysozyme in solution show that they are anisotropic and that their magnitude and nature depend on the physical chemistry of the participating interfaces, suggesting that the nucleation phenomenon is initiated in a nonstochastic fashion (Pellicane *et al.*, 2008).

Understanding the physical principles that govern crystallization at the microscopic level provides the singular underpinning to rationally engineer target proteins to enhance their crystallizability either by improving their solution properties or by increasing their propensity to engage in weak but specific interactions that organize the transformation of nascent clusters into nuclei and drive subsequent crystal growth.

4.3.3. Engineering proteins with enhanced solubility

The solubility of a protein is the primary essential prerequisite for its crystallization. It should be noted that the expression 'low solubility' is often used indiscriminately to describe quite different phenomena, including a propensity to aggregate and precipitate upon overexpression owing to misfolding, amyloid formation and finally genuine low *in vitro* solubility, *i.e.* low protein concentration in equilibrium with the solid phase, of otherwise fully folded and stable proteins (Trevino *et al.*, 2008). Here, the strategies and methods that specifically address the latter case are discussed, *i.e.* precipitation at low concentrations of properly folded proteins.

It has been well established that even single-site mutations of surface residues can dramatically affect the solubility of a protein and its crystallizability (McElroy *et al.*, 1992). Consequently, the intuitively obvious approach is to mutate solvent-exposed hydrophobic amino acids to hydrophilic residues. In this way, the low solubility of the catalytic domain of HIV-1 integrase was addressed by screening 29 mutants in which hydrophobic residues were systematically mutated to hydrophilic amino acids; of the variants tested, the single-site mutant F185K showed a dramatically improved solubility and ultimately yielded X-ray-quality crystals (Dyda *et al.*, 1994; Jenkins *et al.*, 1995). In the case of leptin, the product of the *obese* gene, the solubility-enhancing W100E mutation proved to be critical for crystallization of the protein (Zhang *et al.*, 1997). Recently, a screen of several variants of human apolipoprotein D identified a triple mutant (W99H, I118S, L120S) which was much more soluble than the wild-type protein and which was ultimately used to obtain well diffracting crystals (Nasreen *et al.*, 2006; Eichinger *et al.*, 2007).

While engineering enhanced solubility using site-directed mutagenesis is potentially a powerful approach, in the absence of structural information it is a challenge to predict which hydrophobic residues are solvent-exposed and might therefore constitute useful targets for mutagenesis. Moreover, even if structural information is available for a homologue or the target itself, it may not be clear what type of mutation actually works best, forcing the investigator to rely on extensive screening. This uncertainty arises from the fact that hydrophobicity scales for individual amino acids cannot be used directly to evaluate the increase or decrease of protein solubility as a consequence of a specific mutation. Furthermore, there have been few rigorous studies of the effects of specific mutations on protein solubility. A notable example is a study on ribonuclease SA in which the solvent-exposed Thr76 was replaced by 19 other amino acids and the solubility of all of the variants was carefully evaluated (Trevino *et al.*, 2007). Those variants that contained Asp, Arg, Glu and Ser were the most soluble. Unexpectedly, even though a lysine might be expected to confer higher solubility than a serine or alanine, the T76S mutation actually led to a significantly higher solubility than T76K, while the T76A variant was only marginally less soluble than T76K (Trevino *et al.*, 2007). The authors of the study concluded that mutating Asn and Gln to their respective acids may constitute the most robust strategy of enhancing solubility. Interestingly, one of the first examples of rational enhancement of solubility, *i.e.* the study of trimethoprim-resistant type S1 hydrofolate reductase (Dale *et al.*, 1994), used this very strategy: the amide-containing side chains were systematically substituted with carboxylic amino acids and one specific variant, a double mutant N48E, N130D, was found to exhibit markedly increased solubility and ultimately yielded crystals that were suitable for crystallographic analysis.

Somewhat ironically, large charged residues such as glutamate that confer higher solubility on the target protein may at the same time impede crystallization because they increase the total surface side-chain entropy, making the surface recalcitrant to engaging in crystal contact-mediating interactions. Thus, variants engineered for increased solubility may simultaneously show a decreased propensity to crystallize.

Some of the above uncertainties can be overcome with an alternative approach of directed evolution and phenotypic selection methods, in which soluble mutants are directly selected from vast protein libraries (Farinas *et al.*, 2001; Farinas, 2006; Pédelacq *et al.*, 2002; Waldo, 2003; Cabantous *et al.*, 2005). Several different variations of this method have been reported (Waldo, 2003). For example, the target protein may be fused to the N-terminus of a reporter protein such as the green fluorescent protein (GFP; Waldo *et al.*, 1999) or direct detection methods can be employed to identify soluble variants (Peabody & Al-Bitar, 2001). While elegant and potentially very effective, directed evolution has not yet been widely adopted for the generation of crystallizable proteins.

Solubility problems are not always caused by excessively exposed hydrophobic surfaces. In some cases, the root of the problem is aggregation caused by exposed free cysteines. Reduced cysteines can be identified by alkylation with *N*-ethylmaleimide or iodoacetamide under anaerobic conditions and subsequent electrospray mass spectrometry (Niessing *et al.*, 2004). Several examples illustrate how this approach is helpful in generating samples that are suitable for crystallization. In mitogen-activated protein (MAP) kinase p38α, a single-site mutation (C162S) prevented aggregation and yielded a crystallizable variant (Patel *et al.*, 2004). Similarly, a double mutant (C95K, C142S) of foot-and-mouth disease virus 3C protease showed none of the aggregation problems that plagued the wild-type protein and was subsequently crystallized (Birtley & Curry, 2005). It is noteworthy that in this case an alternative strategy involving mutations of the exposed hydrophobic residues Met81, Leu82 and Val140 did not eliminate aggregation (Birtley & Curry, 2005). In a number of cases aggregation problems were traced to

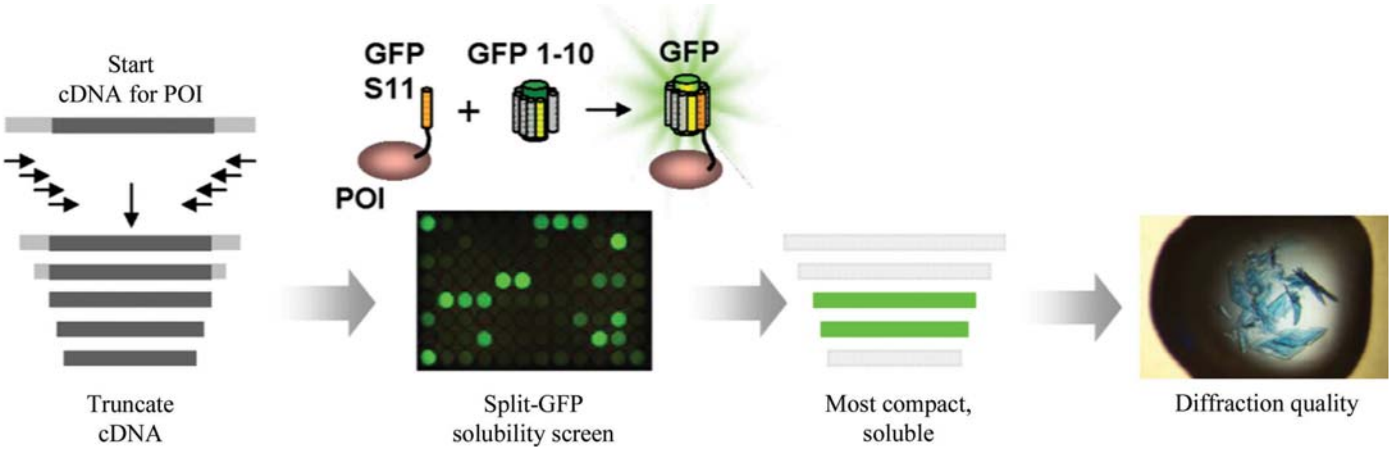

Figure 4.3.4.1
A domain-trapping strategy to engineer soluble variants of a protein of interest (POI) for crystallization using the split-GFP complementation methodology. (Figure courtesy of Dr Geoff Waldo, LANL.)

multiple free cysteines. In She2p, an RNA-binding protein, four cysteines (Cys14, Cys68, Cys106 and Cys180) were mutated to serines in order to overcome oxidation and aggregation (Niessing *et al.*, 2004). In an extreme case, that of human maspin, which is a serpin with antitumour activities, all unpaired cysteines were mutated (C20S, C34A, C183S, C205S, C214S, C297S, C373S) in an effort to obtain a soluble crystallizable variant (Al-Ayyoubi *et al.*, 2004).

4.3.4. Optimization of target constructs

The N- and C-termini of proteins are often flexible and unstructured (Thornton & Sibanda, 1983), creating a potential entropic impediment to crystallization. Initially, the preferred way to circumvent this problem was to use limited proteolysis to trim off the ends, leaving the stable core of the target protein. This strategy remains useful, particularly in its *in situ* version, in which trace amounts of proteases are added directly to crystallization screens (Dong *et al.*, 2007; Wernimont & Edwards, 2009). However, on the downside it introduces the possibility of heterogeneity in the sample owing to incomplete proteolysis. An alternative route is to first identify the smallest functional fragment of the target protein and to then design and overexpress an appropriately modified gene. A number of options are possible. The simplest is the direct prediction of intrinsically disordered regions from the amino-acid sequence alone (Obradovic *et al.*, 2003; He *et al.*, 2009). The functional core units can also be identified experimentally by mass spectrometry following limited proteolysis (Cohen *et al.*, 1995). Alternatively, deuterium–hydrogen exchange coupled to mass spectrometry (DXMS) may be used to identify fast-exchanging amides that map to unstructured fragments (Hamuro *et al.*, 2003; Pantazatos *et al.*, 2004; Sharma *et al.*, 2009).

Importantly, the choice of optimal N- and C-termini may also critically influence the solubility of the target protein. For example, in the case of MAPKAP kinase 2, 16 truncation variants were assayed, all of which contained the catalytic domain, and were shown to have dramatically differing solubilities and propensities for crystallization (Malawski *et al.*, 2006). Similarly, a series of truncations were screened in order to identify a soluble and crystallizable variant of a three-domain fragment of the Vav1 guanine nucleotide-exchange factor (Brooun *et al.*, 2007). In both these cases only a limited number of rationally designed constructs were screened. However, to increase the prospects of success it is also possible to utilize much larger libraries of variants and screen them *in vivo* using the high-throughput split-GFP complementation assay (Fig. 4.3.4.1; Cabantous & Waldo, 2006).

Another troublesome problem associated with flexible termini is their occasional propensity to form multiple intermolecular contacts, leading to crystal forms that contain multiple copies of the target protein in the asymmetric unit. This has been observed, for example, for *Plasmodium falciparum* peptide deformylase, in which removal of three residues from the N-terminus reduced the number of subunits in the asymmetric unit from ten to two (Robien *et al.*, 2004).

In addition to the disordered N- and C-termini, target proteins may contain internal unstructured regions such as subdomains or loops which can be removed or shortened to reduce conformational heterogeneity. For example, the construct used in the successful crystallization of the HIV gp120 envelope glycoprotein had two flexible loops which were replaced with Gly-Ala-Gly linkages to obtain a crystallizable variant (Kwong *et al.*, 1998, 1999). In the case of 8*R*-lipoxygenase the replacement of a flexible Ca^{2+}-dependent membrane-insertion loop consisting of five amino acids by a Gly-Ser dipeptide resulted in crystals that diffracted to a resolution 1 Å higher than the wild-type protein (Neau *et al.*, 2007). An interesting variation of this approach was introduced for the preparation of crystals of the β-subunit of the signal recognition particle receptor. A 26-residue flexible loop was removed, but instead of replacing it with a shorter sequence the authors connected the native N- and C-termini of the protein using a heptapeptide GGGSGGG, thus creating a circular permutation of the polypeptide chain (Schwartz *et al.*, 2004).

Given that the majority of eukaryotic proteins contain at least one stretch of 40 or more disordered residues (Vucetic *et al.*, 2003), optimization of crystallization targets by removal of these sequences is likely to become a routine strategy.

4.3.5. The use of fusion proteins for crystallization

Tags are routinely used in heterologous protein expression in order to enhance folding and solubility and to facilitate purification (Uhlen *et al.*, 1992; Malhotra, 2009). They are either short oligopeptides, such as a hexahistidine, with unique affinity properties or well expressed and highly soluble proteins, such as GST (glutathione *S*-transferase), MBP (maltose-binding protein) or thioredoxin. The tags are inserted into the expression vectors

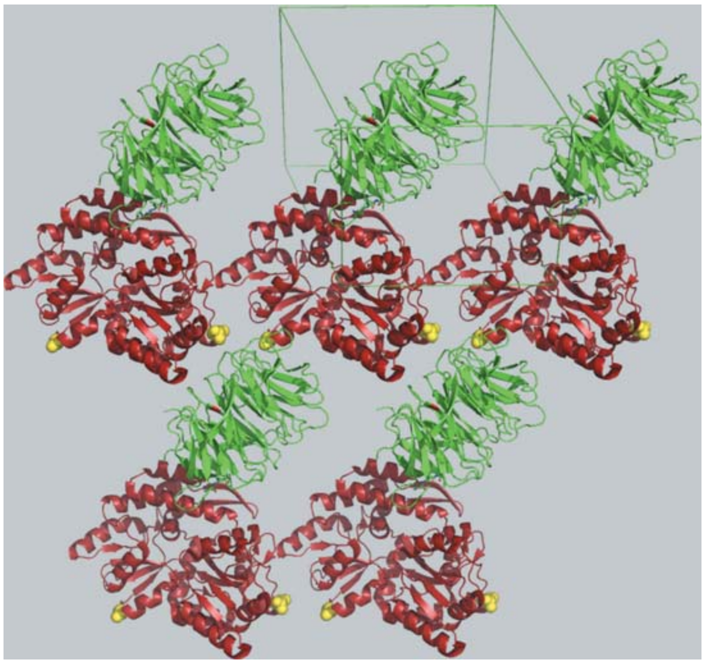

Figure 4.3.5.1
An example of the use of a fused carrier protein in crystallization: the crystal structure of the RACK1 protein (green) crystallized in fusion with an engineered variant of the maltose-binding protein (MBP; red); the major crystal contacts are mediated by MBP (PDB code 3dm0; Ullah *et al.*, 2008). The yellow spheres show alanines introduced by site-directed mutagenesis (see text for further details). Figs. 4.3.5.1 and 4.3.9.1 were generated using *PyMOL* (http://www.pymol.org).

downstream or upstream of the target protein and are often separated from it by a protease-sensitive linker sequence. They are cleaved proteolytically following expression and partial purification of the fusion protein and removed, leaving the isolated target ready for crystallization. However, in some cases the target protein may not be adequately soluble after cleavage or may resist crystallization. One of the possible solutions is to use the intact fusion protein in the crystallization screens in the hope that the carrier protein will both confer solubility on the construct and mediate crystal contacts. Not surprisingly, the canonical carrier proteins, all of which crystallize fairly easily on their own, constitute the obvious first choice. Using this strategy, the DNA-binding domain of DNA replication-related element-binding factor (DREF) was crystallized in fusion with *Escherichia coli* GST (Kuge *et al.*, 1997) and the U2AF homology motif (UHM) domain of splicing factor Puf60 was crystallized as a fusion with thioredoxin (Corsini *et al.*, 2008). A key problem limiting the utility of this technique is the inherent flexibility of a two-domain fusion protein, which is detrimental to its crystallizability. A possible solution to this problem is shortening the linker between the two proteins until a relatively rigid construct is identified (Smyth *et al.*, 2003). This approach was successfully pioneered for maltose-binding protein (MBP), which was used as a fusion chaperone to crystallize the human T-cell leukemia virus type 1 gp21 ectodomain fragment (Center *et al.*, 1998). The same strategy was employed in the crystallization of the ZP-N domain of ZP3 (Monne *et al.*, 2008), the islet amyloid polypeptide (IAPP; Wiltzius *et al.*, 2009) and the MATα1 homeodomain (Ke & Wolberger, 2003). Recently, a genetically modified version of MBP (see below) was used as an N-terminal fusion chaperone to crystallize the signal transduction regulator RACK1 from *Arabidopsis thaliana* (Ullah *et al.*, 2008; Fig. 4.3.5.1). Thus, MBP remains the most successful fusion chaperone for protein crystallization, even though the absolute number of proteins crystallized in this way is still limited.

In addition to the canonical fusion chaperones, which were originally designed as affinity tags, other carrier proteins can be used to assist crystallization. For example, a module made up of two sterile α motif (SAM) domains has been engineered to polymerize in response to a pH drop and was shown to drive the crystallization of 11 target proteins in a pilot study (Nauli *et al.*, 2007). In another example, barnase, a secreted ribonuclease from *Bacillus amyloliquefaciens*, was recently used as a carrier protein for crystallization of the disulfide-rich protein McoEeTI (Niemann *et al.*, 2006).

An alternative to N- or C-terminal fusions is an insertion fusion, in which a carrier protein is inserted into a loop in the sequence of a poorly soluble target. To date, this approach has exclusively been used in membrane-protein crystallization and was initially pioneered for the *E. coli* lactose permease, in which cytochrome b_{562}, flavodoxin and T4 lysozyme were tested as carrier proteins inserted into one of the loops (Privé *et al.*, 1994; Engel *et al.*, 2002). In this specific case none of these variants actually yielded useful crystals and the structure of lactose permease was eventually solved using crystals obtained using a variant containing the C154G mutation which stabilized a single conformation in complex with a lactose analogue (Abramson *et al.*, 2003). In contrast, a similar insertion fusion with T4 lysozyme replacing the third intracellular loop of the β2-adrenergic receptor was highly successful and yielded good-quality crystals that allowed structure determination at 2.4 Å resolution (Cherezov *et al.*, 2007; Rosenbaum *et al.*, 2007). This spectacular result attests to the potential of insertion-fusion proteins, but the method is not trivial as the constructs must be carefully evaluated for both structural and functional consequences of the insertion and a number of variants may have to be screened before a suitable one is identified.

4.3.6. Noncovalent crystallization chaperones

Noncovalent crystallization chaperones, *i.e.* engineered binding proteins that produce noncovalent complexes with target macromolecules, constitute an exciting alternative to fusion carrier proteins. Complexes with such chaperones often exhibit enhanced solubility and/or crystallizability in comparison to the isolated targets. The Fab and Fv fragments of antibodies are most commonly used for this purpose (Kovari *et al.*, 1995; Hunte & Michel, 2002; Prongay *et al.*, 1990; Ostermeier *et al.*, 1995; Jiang *et al.*, 2003; Dutzler *et al.*, 2003; Lee *et al.*, 2005). In its canonical version, the technique requires animal immunization with subsequent purification of hybridoma-derived antibodies and their proteolytic digestion to obtain pure homogeneous Fab fragments (Karpusas *et al.*, 2001; Kovari *et al.*, 1995). Alternatively, the Fab fragment can be directly sequenced and a synthetic gene can be used for *E. coli* expression, although this is not trivial owing to the presence of disulfides and two separate polypeptide chains in an Fab molecule. To overcome this bottleneck, a more efficient method of recombinant production of antibody fragments using mammalian HEK 293T has recently been proposed (Nettleship *et al.*, 2008). Another possibility is the use of so-called nanobodies, *i.e.* single-chain fragments derived from camelid antibodies (Koide, Tereshko *et al.*, 2007; Lam *et al.*, 2009; Korotkov *et al.*, 2009). However, this strategy requires immunization of camels or llamas, which is not technically easy.

Regardless of the specific strategy, the use of hybridoma technology and animal immunization is always time-consuming

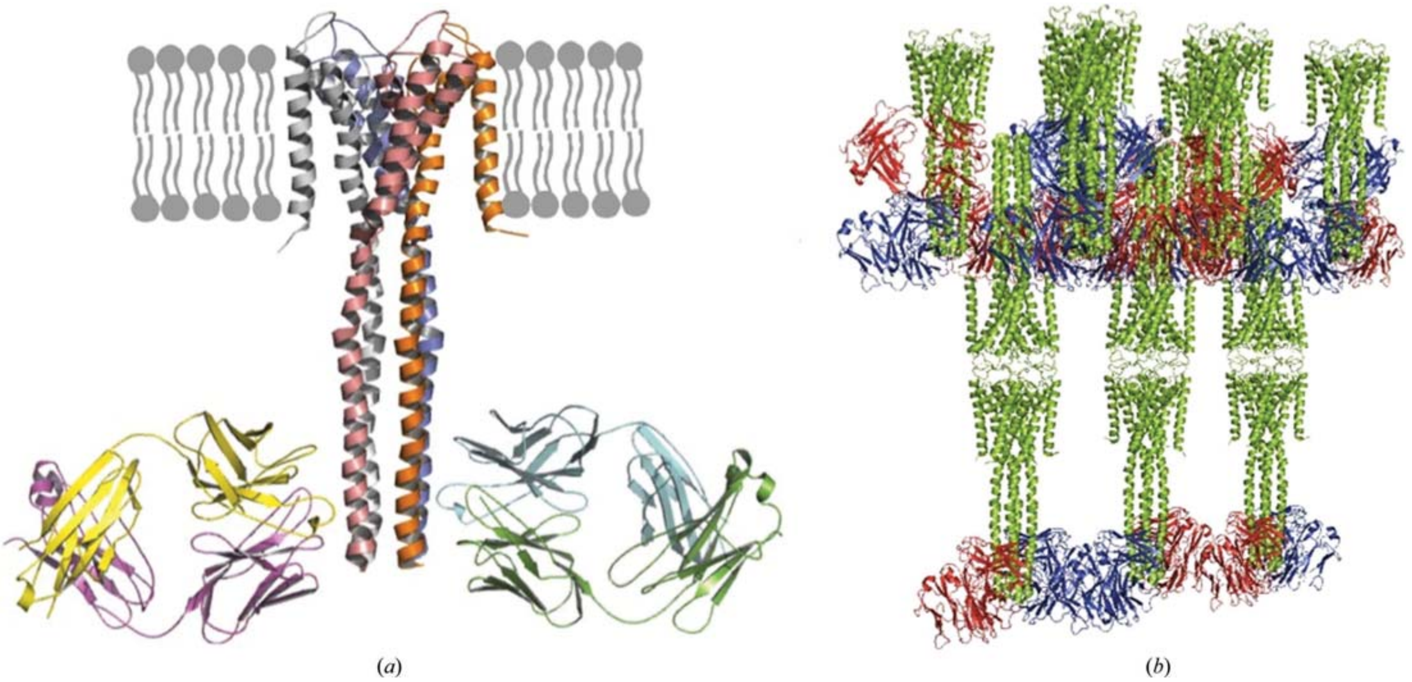

Figure 4.3.6.1
Phage-display-generated Fab fragments as crystallization chaperones: the structure of the KcsA channel in the closed conformation in complex with a synthetic Fab (PDB code 3eff; Uysal *et al.*, 2009). (*a*) A diagram showing how the Fab binds to the cytosolic portion in reference to the transmembrane domain. (*b*) The crystal structure of the complex showing how the synthetic Fab molecules mediate the major crystal contacts. (Figure courtesy of Dr Anthony Kossiakoff, University of Chicago.)

and expensive. In principle, a more efficient approach is to carry out *in vitro* selection of Fab fragments using phage display (Lee *et al.*, 2004) or ribosome display (Lipovsek & Pluckthun, 2004). However, since a typical antibody–antigen interface involves ~30 amino acids, the total number of possible sequences of a given template Fab significantly exceeds the available combinatorial libraries. Consequently, traditional phage-display libraries greatly diminish diversity at the mutated sites, which explains why synthetic antibodies were initially weaker binders than natural ones (Hawkins *et al.*, 1992; Koide, 2009). This problem was successfully overcome using a different type of phage-display library based on a 'reduced genetic code' and comprised of only a few amino acids, *e.g.* four, which produces high-affinity binders based on a single Fab scaffold (Fellouse *et al.*, 2004; Lee *et al.*, 2004). In contrast to natural antibodies, such synthetic Fab fragments can be generated against unique conformations, complexes or weak antigens such as RNA. Among recent examples are the crystallization and structure determination of the closed form of the full-length KcsA potassium channel with its cognate synthetic Fab (Uysal *et al.*, 2009; Fig. 4.3.6.1) and the crystallographic study of the ΔC209 P4-P6 domain of the *Tetrahymena* group I intron, a structured RNA molecule (Ye *et al.*, 2008).

The *in vitro* display methods also allow the engineering of non-antibody scaffolds as alternative protein binders and crystallization chaperones (Koide, 2009). For example, a fibronectin type III domain (FN3) scaffold was successfully used to generate binders with a reduced genetic code phage-display library (Koide, Gilbreth *et al.*, 2007; Gilbreth *et al.*, 2008). A similar approach was used for DARPins, *i.e.* designed ankyrin-repeat proteins (Sennhauser & Grütter, 2008), based on ribosome-display selection (Lipovsek & Pluckthun, 2004; Sennhauser & Grütter, 2008). Several new protein structures have been solved as complexes with DARPin chaperones, including polo-like kinase 1 (Bandeiras *et al.*, 2008), the trimeric integral membrane multidrug transporter AcrB (Sennhauser *et al.*, 2007) and the receptor-binding protein (RBP, the BppL trimer) of the baseplate complex of the lactococcal phage TP901-1 (Veesler *et al.*, 2009).

4.3.7. Removal of post-translational modifications

A number of proteins undergo post-translational modifications which can adversely affect crystallization. By far the most ubiquitous is N- and O-glycosylation, primarily of membrane-associated, secreted and lysosomal proteins. In a number of cases successful crystallization of glycoproteins purified from natural sources has been reported and carbohydrate groups have often been found to be ordered and occasionally sequestered between the protein molecules, thus even contributing in a positive way to crystallization (Mark *et al.*, 2003; Aleshin *et al.*, 1994). In general terms, however, the flexible and heterogeneous carbohydrate moieties, particularly the oligosaccharides linked by N-glycosylation, can account for a significant fraction of the surface area of the protein and can therefore be detrimental to crystallization. The preparation of recombinant proteins in *E. coli* eliminates these post-translational modifications and may sometimes solve the problem (Mohanty *et al.*, 2009), but N-glycosylation is often required for appropriate folding and solubility, so this approach is not always possible. However, if a eukaryotic expression system is a necessity, the problem can often be resolved by mutating the asparagines within the relevant glycosylation motifs (Asn-*X*-Thr/Ser), *e.g.* to aspartates, as was performed in the case of the extracellular domain of the metabotropic glutamate receptor expressed in insect cells (Muto *et al.*, 2009), or to glutamines, as was performed for the human testis angiotensin-converting enzyme (Gordon *et al.*, 2003). Alternatively, glycosylation at these sites can be eliminated by mutation of the Thr/Ser residues in the glycosylation motif to alanine or other amino acids, as described for rat cathepsin B (Lee *et al.*, 1990), or valine, as was the case with the Ebola virus glycoprotein (Lee *et al.*, 2008, 2009). Similarly, potentially glycosylated threonines or serines in O-glycosylated glycoproteins can be mutated to other amino acids (Horan *et al.*, 1998) to avoid or reduce glycosylation.

Other post-translational modifications occur less frequently. Prenylation and N-myristoylation can occur at the C- and N-termini, respectively. Expression in *E. coli*, often using truncated versions of target proteins, is a common remedy (Pai *et al.*, 1990).

4.3.8. Stabilization of protein targets

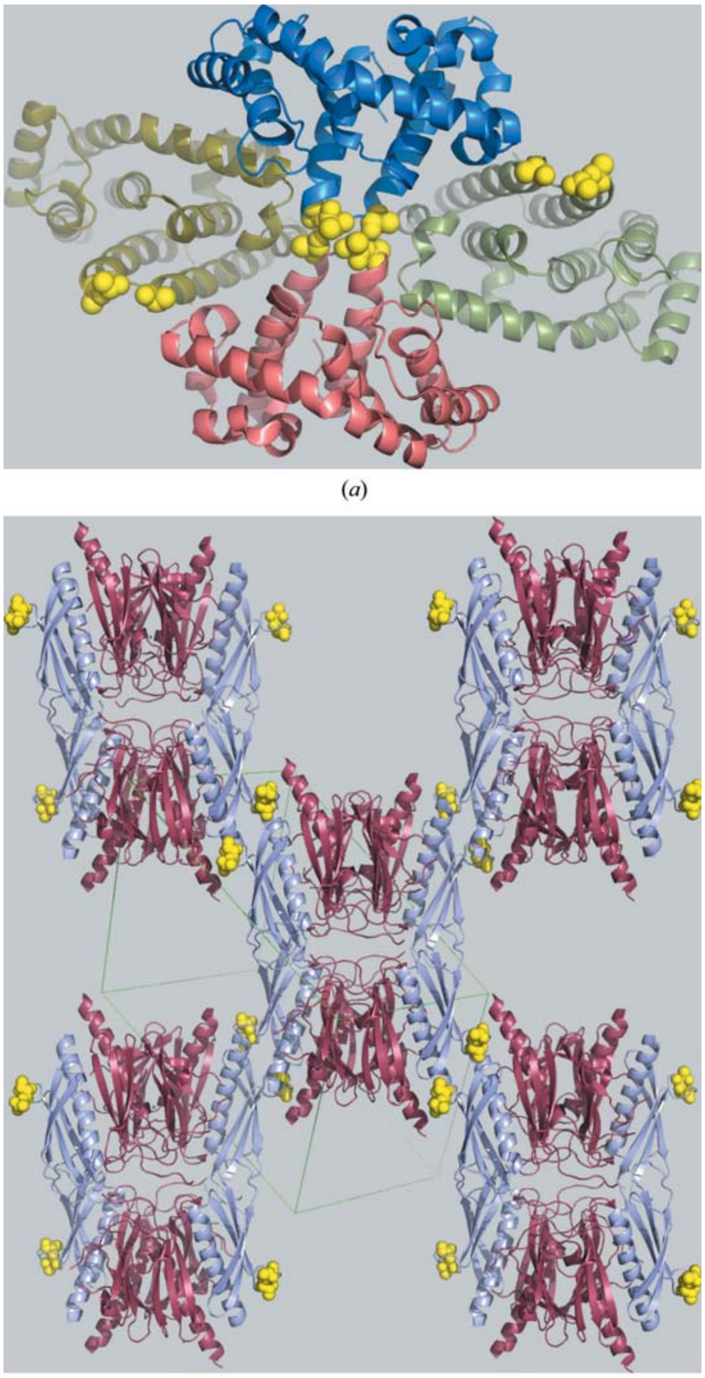
There is currently no clear consensus regarding a possible correlation between the thermostability of a protein and its propensity to form crystals. It is often assumed on the basis of somewhat anecdotal evidence that thermostable proteins are more readily crystallizable and therefore if a specific target protein is recalcitrant to crystallization then a homologue from a thermophilic organism should instead be used. In some cases, low thermostability may correlate with the presence of unstructured loops or termini and consequently the construct-optimization strategies, as described above, are likely to yield a more crystallizable variant with a concomitantly increased stability. For example, a study of MAPKAP kinase 2 showed that truncated variants with increased thermal stability also showed higher crystallization propensity (Malawski *et al.*, 2006). However, it is uncertain whether the relationship is causal or serendipitous. A recent analysis of large-scale data from a structural genomics project showed that when partly or fully unfolded proteins and hyperstable proteins (with melting temperatures T_m of greater than 90 °C) are excluded from comparisons, thermostability *per se* does not correlate with propensity for crystallization (Price *et al.*, 2009). Consequently, it appears that in a general case of a well behaving protein, attempts to increase thermostability by site-directed mutagenesis may not necessarily yield variants with enhanced crystallization properties, although when the prospective crystallization target is inherently unstable, engineering more stable variants may be helpful. In fact, this strategy has been successfully used for membrane proteins, which are often unstable in detergent environments. The first structure of a recombinant G-protein-coupled receptor (GPCR), *i.e.* bovine rhodopsin in complex with 11-*cis* retinal, was obtained using a thermostable variant with an engineered disulfide bond (Standfuss *et al.*, 2007). In the more recent case of the turkey adrenergic $\beta 2$ receptor, 318 variants were screened and six mutations were identified that increased thermostability. A variant containing all six mutations had an apparent T_m that was 21 °C higher than that of the native protein in dodecylmaltoside (DDM), was more stable in short-chain detergents and was successfully crystallized (Warne *et al.*, 2008, 2009). The effort required for such vast screening is substantial, but it appears that within protein families (such as GPCRs) the pattern of mutations enhancing thermostability is preserved, thus making it possible to transfer the mutations from one family member to another (Serrano-Vega & Tate, 2009).

Finally, it should be noted that protein thermostability is strongly dependent on solution parameters such as the ionic strength. In the case of ribonuclease SA, the melting temperature (T_m) increased from ~40 to ~60 °C on transfer from pure 50 m*M* diglycine buffer to 0.9 *M* ammonium sulfate (Trevino *et al.*, 2007). Similarly, binding small molecules, either physiological or non-physiological ligands, typically promote stability (Matulis *et al.*, 2005). High-throughput screening methods have been developed to aid in screening for conditions and ligands that enhance stability (Vedadi *et al.*, 2006; Mezzasalma *et al.*, 2007) and in a general case this strategy appears to hold better promise than attempts to engineer higher stability through mutagenesis.

4.3.9. Surface-entropy reduction (SER)

For well ordered intrinsically stable proteins that show none of the problems addressed above, the propensity of the molecules to associate together and form crystals mediated by weak but specific interactions is ultimately defined by the physical chemistry and topology of the molecular surface. As already pointed out, large flexible amino acids on the surface, such as Lys, Glu and Gln, constitute an impediment to intermolecular interactions and consequently to protein crystallization (Cieślik & Derewenda, 2009; Price *et al.*, 2009). In fact, it has been suggested that these residues and the 'entropy shield' that they form play a role in protein evolution which, given the high average concentration of proteins in cells, disfavours protein–protein interactions unless they are biologically functional (Doye, 2004). Thus, an intuitively obvious way to generate crystallizable variants is to replace selected large and surface-exposed residues with smaller residues such as alanine. This crystal-engineering strategy based on the surface-entropy reduction (SER) concept was extensively tested using as a model system the globular domain of the human Rho-specific guanine nucleotide-dissociation inhibitor (RhoGDI), which is recalcitrant to crystallization in its wild-type form owing to a high content of Lys and Glu residues, which constitute more than 20% of the sequence (Longenecker, Garrard *et al.*, 2001; Mateja *et al.*, 2002; Derewenda, 2004; Cooper *et al.*, 2007). These experiments established that in order to be most effective the SER strategy requires simultaneous mutations of clusters of two to three solvent-exposed high-entropy amino acids, typically Lys, Glu or Gln, located in close sequence proximity. These amino acids are replaced with alanine, although threonine and tyrosine, which is known to make a positive contribution at protein–protein interfaces such as antibody–antigen complexes (Fellouse *et al.*, 2006), can also be used (Cooper *et al.*, 2007). Engineered low-surface-entropy variants of RhoGDI produced new and unique crystal forms, many with superior diffraction quality when compared with the wild-type protein. Importantly, in the vast majority of these crystals the mutated surface patches mediated crystal contacts, suggesting that SER engineering directly drives crystallization in a rational fashion by creating suitable crystal-contact-forming interfaces. The general utility of the method was further established by the crystallization of several novel protein targets found to be recalcitrant to crystallization in their wild-type form (Longenecker, Lewis *et al.*, 2001; Derewenda *et al.*, 2004; Devedjiev *et al.*, 2004; Janda *et al.*, 2004).

SER is quickly becoming a method of choice for engineering crystallizable variants of both individual proteins and protein–protein complexes. To date (December 2009), there have already been more than 100 depositions made to the Protein Data Bank (Berman *et al.*, 2007) based on diffraction studies of crystals generated by SER and corresponding to 47 novel structures, seven novel protein–protein complexes, several studies of proteins in complexes with drug leads aimed at rational drug development and two membrane proteins. The current list of crystal structures obtained using SER crystals includes a number of cases of exceptionally high biological interest. For example, the EscJ protein from enteropathogenic *E. coli*, the oligomerization of which initiates assembly of the type III bacterial secretion system, was crystallized with three entropy-reducing mutations (E62A, K63A and E64A) forming a key contact in the crystal structure (Yip *et al.*, 2005). Likewise, the HIV CcmK4 capsid



(a)

(b)

Figure 4.3.9.1
Two examples of proteins crystallized by the surface-entropy reduction (SER) method. (*a*) The RGSL domain of the PDZRhoGEF nucleotide-exchange factor (PDB code 1htj; Longenecker, Lewis *et al.*, 2001); the yellow spheres show the alanines introduced by mutagenesis, which mediate an isologous crystal contact across a crystallographic twofold axis. (*b*) The crystal structure of EpsI complexed with EpsJ (PDB code 2ret; Yanez *et al.*, 2008); the EpsI protein (pale blue) contains two surface mutations, shown by yellow spheres, which mediate heterologous crystal contacts.

protein only crystallized after an entropy-reducing mutation (E104Y) was introduced into the protein (Pornillos *et al.*, 2009). The protein–protein complexes solved to date underscore the utility of the method, which extends beyond individual proteins because high-entropy patches occur outside complex interfaces. For example, the complex of c-Src and its inactivator Csk was crystallized using a variant of Csk carrying K361A and K362A mutations (Levinson *et al.*, 2008). Similarly, it was possible to crystallize the complex of two pseudopilins EpsI and EpsJ from the type 2 secretion system of *Vibrio vulnificus* when a variant of EpsI carrying two mutations (E128T and K129T) was used (Yanez *et al.*, 2008; Fig. 4.3.9.1).

An interesting variation of the SER method was used in the investigation of the RACK1 protein, which was crystallized as an in-line fusion with an MBP variant carrying D82A, K83A and K239A mutations (Ullah *et al.*, 2008). This is the first example of the application of the surface-entropy reduction strategy to a carrier protein and not the crystallization target itself.

The SER strategy is attractive not only because of its efficacy but also because of its simplicity: once an expression construct for a target protein is available several rounds of mutagenesis can easily create variants with systematically enhanced crystallizability. To assist in the design of crystallizable variants, a server has been developed that uses the amino-acid sequence of the target to identify suitable mutation sites (Goldschmidt *et al.*, 2007).

4.3.10. Improvement of crystal quality

In most cases, protein engineering is used as a tool of last resort to obtain variants for proteins for which no crystals can be grown using the wild-type form. However, it may sometimes be necessary to obtain a new, different crystal form even when the wild-type protein does crystallize. Such a need may arise, for example, in drug-design investigations, where high-resolution structures are particularly critical for evaluation of the interactions between lead compounds and the target protein and may not always be possible using wild-type crystals. A novel crystal form may also be necessary if the wild-type crystals contain the target protein in an orientation in which the active site is obscured by crystal contacts, making it impossible to soak in drug lead compounds and screen small-molecule libraries by high-throughput crystallography (Blundell & Patel, 2004).

One possible strategy for obtaining a new crystal form is to modify the existing crystal contacts by replacing some of the participating amino acids. While this approach occasionally leads to improvement of the X-ray data resolution (Liu *et al.*, 2007; Mizutani *et al.*, 2008), modification of crystal contacts is typically counterproductive as it abolishes the propensity of the target to crystallize in one form but does not necessarily induce another (Charron *et al.*, 2002). A more successful strategy is to generate a novel crystal form by engineering new crystal contacts through SER. For example, a novel crystal form of the insulin-like growth factor 1 receptor kinase domain, a putative drug target, was obtained using a double mutant (E1067A and E1069A); the new form diffracted to 1.5 Å resolution, whereas the wild-type crystals only diffracted to 2.7 Å resolution (Munshi *et al.*, 2003). In the case of the catalytic domain of activated factor XI, a key enzyme in the blood coagulation cascade and another potential drug target, a single K437A mutation allowed the preparation of a crystal form that diffracted to 2.0 Å resolution (Jin *et al.*, 2005). Entropy-reducing mutations were also key in the preparation of a crystal form of HIV-1 reverse transcriptase for structure-based drug design that diffracted to 1.8 Å resolution, in contrast to the typical 2.5–3.0 Å range observed for the wild-type protein crystals (Bauman *et al.*, 2008).

4.3.11. Conclusions

Protein engineering has become a routine tool that is used to generate crystallizable macromolecules and their complexes. While some approaches may only apply to very specific targets, a number of strategies offer general applicability. Among these, gene-construct optimization or surface-entropy reduction are quickly gaining popularity as methods of choice. However, it should be stressed that none of the methods described here offer a guarantee that the target protein can be coerced to crystallize. To maximize the chances of success, one must frequently attack the problem on multiple fronts based on an understanding of the chemical and physical properties of a specific protein. This is particularly true of technically difficult targets such as membrane proteins. A classic example illustrating this principle is the study of the HIV gp120 envelope glycoprotein (Kwong *et al.*, 1998, 1999). The construct that was ultimately used in successful crystallization screens had deletions of 52 and 19 residues from the N- and C-termini and two flexible loops replaced by Gly-Ala-Gly linkages; additionally, the protein was 90% deglycosylated compared with the wild type. Moreover, this engineered gp120 was only crystallized in the form of a ternary complex with the CD4 receptor and an Fab fragment from a neutralizing antibody. In the recent case of the ATP-gated P2X4 ion channel, a crystallizable variant was obtained after a series of N- and C-terminal deletions were screened to identify the smallest functional unit and the introduction of three mutations (C51F/N78K/N187R) to eliminate both aggregation arising from oxidation and N-glycosylation (Kawate *et al.*, 2009).

The rapidly expanding database of macromolecular structures greatly enhances our understanding of the physical chemistry of proteins, ultimately enhancing our ability to predict the behaviour of a protein in solution from its sequence. It is therefore increasingly possible to rely on such theoretical predictions *in lieu* of tedious experimental screens. A number of online tools have been developed for this purpose. The propensity of a protein target to crystallize can be evaluated using the *XtalPred* server (http://ffas.burnham.org/XtalPred-cgi/xtal.pl), which offers insights into potential sources of problems arising from sequence features (Slabinski *et al.*, 2007). Automated design of optimally truncated constructs for structural analysis has been made possible by the *ProteinCCD* meta-server (http://xtal.nki.nl/ccd), which uses the cDNA sequence of the target (Mooij *et al.*, 2009). This server collects information about secondary structure, disorder, putative coiled coils, transmembrane segments, domains and domain linkers, and suggests constructs so that the user can interactively choose suitable options and obtain sequences of oligonucleotides needed for appropriate PCR amplification (Mooij *et al.*, 2009). For proteins recalcitrant to crystallization in their wild-type form, surface mutations enhancing crystallizability can be designed using the surface-entropy reduction server (http://nihserver.mbi.ucla.edu/SER/; Goldschmidt *et al.*, 2007).

As the focus of macromolecular crystallography shifts from the principles of protein architecture to increasingly complex biological questions, the approach to crystallization is also undergoing dramatic evolution. As we gain better understanding of the microscopic nature of protein crystallization, we will be able to develop rational protein-engineering strategies that systematically and significantly improve the success rate of crystallization.

The research on protein crystallization in my laboratory is supported by the National Institute for General Medical Sciences. I am greatly indebted to Drs Urszula Derewenda, Anthony Kossiakoff, Alexander McPherson, Geoff Waldo and David Cooper for discussions and comments on the early version of the manuscript.

This chapter is based on a recent article published in *Acta Crystallographica Section D* (Derewenda, 2010).

Chapter 4.4. High-throughput X-ray crystallography

K. H. Choi

4.4.1. Introduction

Structural-genomics projects have contributed to major developments in automation, miniaturization and process integration in X-ray crystallography. In the structural-genomics approach, multiple open reading frames from a genome are separately cloned and expressed without prior knowledge of the structure or function of the encoded proteins. Essential steps in a typical project include: (1) bioinformatics analysis of genome sequences for potential targets, (2) gene amplification by PCR (polymerase chain reaction) and subcloning into an appropriate expression vector, (3) protein expression and purification, (4) protein crystallization, (5) X-ray data collection, and (6) data processing and structure determination. Structural-genomics projects typically operate under a 'lowest hanging fruit' philosophy, pursuing structural targets that prove to be the most amenable to crystallization. However, for individual investigators working on specific problems, it is often necessary to focus on a particular protein. Many of the protocols developed in high-throughput (HT) structural genomics can also be adapted for parallel production of multiple constructs of a single protein target which is difficult to crystallize. This chapter summarizes recent developments in HT X-ray crystallography approaches and their application to parallel production of a single protein (Gräslund, Nordlund *et al.*, 2008; Manjasetty *et al.*, 2008; Sharff & Jhoti, 2003).

4.4.2. Design of multiple constructs: bioinformatics analysis of genome sequences

Often, the two primary bottlenecks in crystal structure determination are obtaining a soluble protein and the initial crystallization. If initial crystallization trials do not lead to successful crystallization, diffraction-quality crystals or structure determination, modification of the protein itself is often more successful in producing useful crystals than exhaustive screening/optimization of protein crystallization conditions. In the HT approach, generation of stable domains having variable N or C termini can be performed in parallel, vastly reducing time and resource requirements. The clones can be screened systematically for soluble, active proteins amenable to crystallization. This approach is particularly suited to problems in which one has no estimate, *a priori*, of which constructs are likely to be most successful at the expression, purification or crystallization steps.

It may be difficult to predict which modifications will influence protein solubility and the protein's ability to crystallize. A common and often useful strategy is to crystallize a similar protein from an alternative biological source. If an alternative source is either unavailable or equally problematic, gene fusion with large affinity tags can be used for increasing protein expression and solubility. Several fusion proteins, including thioredoxin, maltose binding protein, glutathione S-transferase, intein, SUMO (small ubiquitin-like modifier) protein and calmodulin-binding protein, have been used to generate soluble proteins. However, the fused tag may prevent crystallization because of conformational heterogeneity resulting from a flexible linker; hence, the tag must often be removed in an additional purification step. Protein engineering by amino-acid substitutions and chemical modifications (such as methylation of exposed lysines) have been shown to improve crystallization of some proteins (Rayment, 1997; Walter *et al.*, 2006; Wingren *et al.*, 2003). Large, flexible solvent-exposed residues (*e.g.* Lys or Glu) on the surface of proteins are substituted with smaller residues (*e.g.* Ala) to facilitate the formation of intermolecular contacts which stabilize the crystal lattice (the surface-entropy reduction approach; Cooper *et al.*, 2007; Derewenda, 2004). Random mutagenesis following selection of a desired phonotype (*e.g.* folding ability using a GFP (green fluorescent protein) reporter or solubility assays) has been used to produce soluble proteins from insoluble wild-type proteins (the directed-evolution approach; Pédelacq *et al.*, 2002). Since symmetric molecules such as homodimers may crystallize more readily than monomeric protein, new Cys residues can be introduced in a monomeric protein to induce homodimer formation *via* intermolecular disulfide bond formation (the synthetic symmetrization approach; Banatao *et al.*, 2006).

Bioinformatics tools, including multiple sequence alignment and sequence motif searches, as well as prediction of secondary structures, domain boundaries, membrane spanning and disordered regions, can be used to aid the rational design of constructs. General considerations in designing truncation mutations are to avoid truncations in the middle of predicted secondary structural elements, to avoid hydrophobic residues at the termini, and to eliminate membrane-spanning regions in the construct design. In the case of multi-domain proteins, truncation of the protein to smaller functional domains can be effective. Exact locations of the beginning and ending of a domain are still difficult to predict even with domain search programs, and thus biochemical approaches such as limited proteolysis can aid the determination of the domain boundaries. The optimal step size for truncation mutations cannot be predicted, but protein constructs varying by approximately five residues in length often show significant differences in solubility and crystallization behaviour (Choi *et al.*, 2004; Gräslund, Sagemark *et al.*, 2008).

4.4.3. Cloning

Development of robotics that utilize a 96-well format has changed traditional sequential cloning of individual proteins such that parallel HT cloning and protein preparation are now possible. The conventional steps in cloning are PCR amplification, restriction enzyme digestion, ligation, transformation, selection of transformers and protein expression tests. Many procedures, including amplification of target genes, cloning and screening for expression, can be achieved in parallel (96 samples at a time) using either a single liquid-handling robot or multichannel pipettors. In 96-well parallel cloning, reaction steps for individual wells cannot be optimized, and thus care should be taken to synchronize all reactions and to minimize the number of steps to increase efficiency. For this reason, certain cloning strategies are more popular for HT cloning. Recombinant protein

Figure 4.4.3.1
Diagram of HT cloning, expression and purification. All steps can be performed in a 96-well format except the step labelled with an asterisk (*). (*a*) PCR amplification. PCR products are loaded onto an E-gel (1% agarose) in a 96-well format with a molecular marker (lane 'M') and visualized with ethidium bromide. A close-up view of the gel outlining individual wells is also shown. (*b*) Transformation. Transformed cells were plated in 48-well agar plates. (*c*) Protein expression was tested using a western dot blot. H1 and H7 are negative and positive controls, respectively. (*d*) Small-scale purification using affinity resin. A 96-well filter plate in small-scale protein purification steps (left) and a 96-well pre-cast protein gel electrophoresis system (right) are shown. (*e*) Crystallization robot for setting up 96-well crystallization plates (right). (*f*) Crystal imaging and scoring system. A close-up view of an image of well B10 is shown on the right.

expression in *E. coli* is the most common, and will be discussed here.

4.4.3.1. Ligation-independent and recombination cloning

Ligation-independent cloning (LIC) strategies remove the need for restriction enzyme digestion and ligation of PCR products, and are thus ideal for use in an HT cloning procedure. In LIC, PCR primers are designed to append sequences that, after treatment with T4 DNA polymerase, generate 12- to 15-base overhangs that are complementary to overhangs in the vector (Aslanidis & de Jong, 1990). These longer cohesive ends make the insert–vector complex sufficiently stable to allow the transformation of hosts without ligation of the fragments.

The recombination strategy is based on the site-specific recombination reaction involved in bacteriophage λ integration and excision (Hartley *et al.*, 2000). PCR primers are designed to contain the specific sequences of recombination at $5'$ and $3'$ ends of the target gene, and the resulting PCR product is subcloned into a shuttle vector *via* site-specific recombination in the presence of integrase, integration host factor proteins and excisionase (*e.g.* the Gateway cloning system from Invitrogen). This clone can then either be isolated after transformation or directly used without purification for cloning into an expression vector. The major advantage of recombination cloning is that it provides a convenient way to shuttle an insert from one vector to another and thus is useful to test multiple expression conditions.

4.4.3.2. Practical application

Since the PCR reaction must be synchronized for all 96 wells in a plate, PCR primer design is important for the success of the PCR reaction. All PCR primers should have similar melting temperatures, between 50 and 60 °C. PCR products and the prepared vector are mixed and transferred into competent cells aliquoted into a 96-well plate. The PCR products and other DNA samples during the cloning, including the restriction-enzyme digest or a plasmid preparation (if needed), can be analysed *via* gel electrophoresis using a commercially available 96-well agarose gel (E-gel 96 from Invitrogen) in less than 15 min. The gel is compatible with a 96-well format and can be loaded either with a liquid-handling robot or multi-channel pipettor (Fig. 4.4.3.1*a*). The PCR step usually results in success rates as high as 98%. DNA purification kits are available in a 96-well format that use a vacuum manifold. As described above, the restriction-enzyme digest and ligation steps are not necessary in some cloning strategies.

Following transformation, cells are then plated into two 48-grid agar growth plates mixed with appropriate antibiotics (Fig. 4.4.3.1*b*). The 48-grid agar plate is made by inserting a cloning grill into a square Petri dish before pouring the agar, and the grill remains embedded in the media. Small glass beads can be added to each segment of the 48 grids to spread the solution. Colonies are picked by a colony picker, and are grown in 96-well deep-well blocks containing media and appropriate antibiotics. Using a liquid-handling robot and a colony picker for a single round of cloning, it is possible to achieve >80% efficiency in a 96-well format. The same robotic setup can be used for the subsequent recovery of recombinant plasmid before DNA sequencing and protein expression.

4.4.4. Protein expression and purification

Small-scale protein expression in an HT format enables evaluation of the expression, solubility and purification of target proteins or multiple constructs. Autoinduction allows many protein expression tests in parallel without having to monitor cell densities to optimize induction, and is thus ideal for HT approaches. Each protein in a 96-well plate will have different chemical properties and sizes, and thus affinity tags are the method of choice for parallel purification of multiple proteins on a single platform. Dot blots can be used to test expression or solubility, and miniaturized resin deposited in a 96-well plate can be used for a purification test. Although up to 90 µg of protein have been purified from 1 ml of *E. coli* cell culture (Scheich *et al.*, 2003), the amount of protein obtained from small-scale purification is generally not enough for initial crystallization trials, even with low-volume crystallization, and thus scaled-up protein production and purification is needed. The purification tags can be removed upon large-scale purification.

4.4.4.1. Autoinduction

Protein expression under control of the T7 *lac* promoter system can be induced either with the chemical inducer isopropyl-β-galactoside (IPTG) or by autoinduction using a mixture of glucose, glycerol and lactose during *E. coli* growth. In autoinduction, cells grow to relatively high density in a defined ratio of glucose-to-lactose media (Studier, 2005). Initially, glucose prevents induction by lactose. When available glucose is used up, lactose then induces target protein expression switching to lactose metabolism.

Cell cultures (1 ml) are grown in 2.2 ml deep-well 96-well blocks. Protein expression is autoinduced using commercially available glucose/lactose media (*e.g.* Overnight Express from EMD Biosciences). The following day, cells are lysed either by repeated freezing and thawing cycles, or by addition of a lysozyme solution. A combination of lysozyme and benzonase solutions (*e.g.* PopCulture reagent from Novagen) eliminates the need for cell harvesting prior to lysis and lysate clarification following lysis. The cell lysate can then be directly used for expression and purification tests. Alternatively, whole-cell lysates can be filtered though a 96-well filter plate, allowing for separation of inclusion bodies from the soluble fraction (filtrate) so that protein expression in the soluble fraction can be assessed.

4.4.4.2. Expression and solubility test: dot blot

Dot blot is a simple method that can be used to analyse either total protein expression in the cell lysate, or soluble protein expression following the separation of supernatant and cell pellet. Protein samples from the total cell lysate in a 96-well plate are dotted onto a nitrocellulose membrane by applying a vacuum. Target proteins are then probed with an antibody against the protein or against an affinity tag, *e.g.* anti-His-tag antibody for His-tagged protein detection (Fig. 4.4.3.1*c*). Alternatively, the cell lysates are analysed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) for protein expression using a pre-cast 48- or 96-well SDS gel (E-PAGE 48 or 96 from Invitrogen). The gel consists of 48 or 96 wells for samples, and an additional four or eight wells for protein markers. The protein can be loaded either with a liquid-handling robot or with a multichannel pipettor, and electrophoresis is completed within 15 min (Fig. 4.4.3.1*d*).

4.4.4.3. Small-scale purification

Affinity purifications are preferred in a 96-well format because the specific interaction between the protein and affinity resin allows for a simple ‘bind–wash–elution’ procedure. Purification using a His-tag or a GST-tag (where GST = glutathione S-transferase) is popular in structure determination projects, and appropriate resins are available as magnetic beads or agarose resin in a 96-well plate, *i.e.* magnetic Ni-NTA or GST beads, or Ni- or Co-linked agarose discs, respectively.

The soluble fraction or whole-cell lysate is transferred to a 96-well plate containing an affinity resin for protein binding. The beads are separated from unbound protein by placing them in a magnetic stand designed to accommodate a 96-well format, or by filtration using a 96-well filter plate that retains the beads but allows passage of the cell lysate. Beads are washed, and bound protein is then eluted with the appropriate elution buffer (*i.e.* imidazole and reduced glutathione for His-tagged and GST-tagged proteins, respectively) into a 96-well plate by applying a vacuum (either as part of an appropriately equipped liquid-handling robot, or by using a 96-well vacuum manifold) or by centrifugation. Purified proteins are analysed by SDS–PAGE using a pre-cast 48- or 96-well protein gel. The gels can then be stained either by protein staining or western blotting. A new system for protein and DNA analysis has been developed based on a microfluidic chip (Caliper Labchip, Caliper Life Science). These chips contain a network of miniaturized channels, through which fluids and chemicals are moved to separate DNAs or proteins. The DNA and protein signal is measured by laser-induced fluorescence. The instrument is capable of separating 2 ng–2 µg amounts of protein, one well after another; it takes about 1 h to analyse a 96-well plate.

4.4.5. Crystallization

HT crystallization using 96-well crystallization plates greatly reduces the total amount of protein required for screening and thus structure determination. Robotic crystallization systems are capable of dispensing nanolitre droplets (<100 nl) and hence substantially increase the number of conditions that can be screened with a fixed amount of protein sample, as well as reducing the time required for setting up a series of crystallization trials. A thousand conditions with different crystallization parameters (*e.g.* pH, salts, temperature) can be screened with 100 µl of protein sample. At the time of writing, commercially available crystallization robots include the Honey Bee (Cartesian Micro-array), Phoenix (Rigaku), Mosquito (Molecular Dimensions Limited) and Oryx (Douglas Instrumentation). These crystallization robots can set up either vapour-diffusion, microbatch or hanging-drop methods in 96-well plates within 15 min. Crystallization robots can also be integrated into a larger system that includes storage and imaging of crystallization plates, and liquid-formulation robots.

Honey Bee and Phoenix robots contain a single (or several) non-contact channel that dispenses protein solution and a 96-channel dispenser head that dispenses the crystallization solutions (50 nl to 100 µl). The 96-channel head transfers crystallization solutions from a 96-well deep-well plate into the reservoir and crystallization drop in a 96-well crystallization plate (Fig. 4.4.3.1*e*). A single channel transfers protein solution into each of the 96-well drops one by one without touching the precipitate drops. The plate is then sealed with a clear film by the user. The Mosquito liquid-handling robot can set up drops with a hanging-drop geometry, and is more popular with membrane protein crystallization (detergent solutions have a tendency to adhere to the side of the drop well in sitting-drop geometry). The Mosquito uses only disposable tips capable of dispensing 20 nl–1.2 µl volume; thus the user can control the location of drop deposition more precisely because the disposable tips can touch the drop. The use of disposable tips also prevents cross-contamination between samples, and washing steps between samples are eliminated.

The Fluidigm TOPAZ system utilizes a new technology, the crystallization screen chip, in which protein sample and reagent solutions are automatically loaded into diffusion chambers within the protein screen chip and the two solutions mixed by free interface diffusion, as opposed to vapour diffusion or microbatch techniques (Thorsen *et al.*, 2002). A very small amount of protein is required for a crystallization screen, *i.e.* as little as 1.0 µl protein solution for 96 trials. Crystals obtained from the protein chip are generally too small for X-ray data collection, and thus need to be scaled up to obtain diffraction-quality crystals.

Progress of crystallization trials from large numbers of 96-well plates can be monitored using an imaging robot to take pictures of individual crystallization drops. The resulting images can then be analysed either manually or using automatic crystal recognition systems at specified time intervals (Markley *et al.*, 2009). Remote viewing of recorded crystal pictures is also available over the web. Each recorded image is linked to crystallization conditions for evaluation and scoring of the crystallization conditions (Fig. 4.4.3.1*f*). Minstrel (Rigaku), CrystalFarm (Bruker) or HomeBase (The Automation Partnership) systems offer integrated systems for plate storage and imaging.

Crystallization conditions that initially produced crystals should be optimized to improve crystal growth and quality. A liquid-handling robot can be used to make screens in 96-well deep-well plates. A liquid-formulation robot has been developed for protein crystallization to make grid screens of 96-well deep-well conditions (*e.g.* Alchemist from Rigaku). The crystallization conditions stored in an imaging robot are linked to the liquid-formulation software, and can be used to formulate 96-well screen conditions for optimization experiments. Other optimization methods such as crystallization in gels, control of nucleation using oil mixtures or microporous materials, and seeding experiments can also be employed in an HT fashion (Chayen, 2003; Georgiev *et al.*, 2006; Sugahara *et al.*, 2008).

4.4.6. Synchrotron data collection

High-brilliance beamlines at modern synchrotrons have significantly reduced the time required for X-ray data collection, and complete data sets can often be collected within minutes. Thus, the time required for crystal mounting and centring is no longer negligible. Automatic crystal mounting and centring allow users to remotely mount crystals for crystal evaluation and data collection without entering the experimental hutch (Manjasetty *et al.*, 2008; Sharff & Jhoti, 2003; Sugahara *et al.*, 2008).

Automated crystal mounting allows the screening of many crystals for diffraction quality and then goes back to the best diffraction-quality crystals for full data collection. The mounting robot picks up frozen crystals in a pin from a Dewar, puts them on a goniometer and retrieves the pin after the diffraction test. The automated crystal-mounting robots have primarily been developed for use at synchrotron sources, although a commercial version of an automatic sample-mounting robot is now available that can be used with a home-source X-ray generator (ACTOR from Rigaku and cryogenic sample changer from Marresearch). Fully automated crystal alignment is not yet available, but semi-automated crystal centring by clicking a mouse to indicate the intended centre of the crystal is used at most beamlines.

PART 5. CRYSTAL PROPERTIES AND HANDLING

Chapter 5.1. Crystal morphology, optical properties of crystals and crystal mounting

H. L. Carrell and J. P. Glusker

5.1.1. Crystal morphology and optical properties

When crystals of a biological macromolecule are grown, they are first examined under the microscope. This can show the crystal quality and may reveal crystal symmetry. Some external properties of macromolecular crystals are described here, including information on shape, habit, polymorphism, twinning and the indexing of crystal faces. Optical properties are also described. Every crystal form, however, has to be treated individually; only by working with it can the crystallographer discover its physical properties. The diffractionist aims to be able to mount a macromolecular crystal in a totally stable manner so that it does not deteriorate or slip in position during the data collection. Some methods for mounting such macromolecular crystals for X-ray diffraction studies are described here together with the necessary tools. For general information on purchasing supplies to do this see the list at http://www.hamptonresearch.com.

5.1.1.1. Crystal growth habits

5.1.1.1.1. The shape of a crystal – growth habits

Morphology is the general study of the overall shape of a crystal, that is, the arrangement of faces of a crystal. It can often provide useful information about the internal symmetry of the arrangement of atoms within the crystal (Mighell *et al.*, 1993). The periodicity of the arrangement of molecules or ions in a crystal can be represented by three non-collinear vectors, **a**, **b** and **c**, which give a unit cell in the form of a parallelepiped with axial edges a, b and c, and interaxial angles α, β and γ (α between **b** and **c**, *etc.*). The vectors **a**, **b** and **c** from the chosen origin of the unit cell are, by convention, selected in a right-handed system. Since there may be several possible choices of unit cell, the simplest, with the smallest possible repeats and with interaxial angles nearest to 90°, is the best choice. One method used to highlight the periodicity of the atomic arrangement within a crystal is to replace each unit cell by a point; this mathematical construction gives the crystal lattice. The entire crystal structure is the convolution of the unit-cell contents with the crystal lattice.

Biological macromolecules are, in general, chiral and can only crystallize in those space groups that do not contain symmetry operations that would convert a left-handed molecule into a right-handed one (improper symmetry operations). Proper symmetry operations involve translations, rotation axes and screw axes. These maintain the chirality of the molecule and hence are appropriate for crystals of biological macromolecules. The number of possible space groups is therefore reduced by this constraint on the types of symmetry operations allowed from the usual 230 for molecules in general down to 65 for chiral molecules.

The appearance of a crystal that has grown under a particular set of experimental conditions is called its habit. It is a result of the different relative growth rates of various crystal faces, and these rates, in turn, depend on the nature of the interactions between the molecules in the crystal, the degree of supersaturation of the solution and the presence of any impurities which may affect the growth rates of specific crystal faces. The term 'habit' is only used to describe the various appearances of crystals that are composed of identical material and maintain the same unit-cell dimensions and space group. The faces that have developed on these crystals are various subsets of those implied in the overall morphological description of the crystal. Any change in the experimental conditions under which a crystal is grown may alter its habit; a judicious selection of experimental conditions may permit formation of crystals with a chunky habit that are more suitable for X-ray diffraction analysis than thin plates or needle-like crystals. Examples of the crystalline forms of haemoglobins are provided by Reichert & Brown (1909).

Various descriptions of crystal habits appear in the literature. These include terms such as 'tabular', 'platy' or 'acicular' crystals, 'hexagonal rods' and 'truncated tetragonal bipyramids', among others. Some crystal habits are not very appropriate for X-ray diffraction analyses; these include spherulites, which are polycrystalline aggregates of fine needles with an approximately radial symmetry, and dendrites, which have a tree-like structure. The habit of a crystal can sometimes give information on the molecular arrangement within it. For example, flat molecules that stack readily upon each other produce long crystalline needles, because interactions in the stacking direction are stronger than those in other directions.

A crystal is bounded by those faces that have grown most slowly. Fast-growing faces quickly disappear as more and more molecules are deposited on them, constrained by surrounding faces that are growing more slowly. Any factor that changes the relative rates of growth of crystal faces, such as impurities in the crystallizing solution, will affect the overall habit. Different faces of protein crystals have different arrangements of side chains on their surfaces; thus, an impurity may bind to certain faces rather than others. Adsorption of an impurity on a particular face of a crystal may retard the growth of that face, causing it to become more prominent than normal in the growing crystal.

5.1.1.1.2. Quality of protein crystals

Protein and nucleic acid crystals contain a high proportion of water in each unit cell and are therefore fragile. The proportion of solvent to macromolecule in the crystal can be expressed, as described by Matthews (1968), as V_m in $\text{\AA}^3\,\text{Da}^{-1}$ for the asymmetric unit. Values in the range 1.7 to 4.0 are usual for proteins, but nucleic acid crystals generally have a higher water content. Crystal fragility due to water content may be used to determine whether or not a crystal contains protein or buffer salt. Pressure with a fine probe will settle this question because a protein crystal will shatter, while a salt crystal, which is much sturdier, will generally withstand such treatment. If crystals have grown into one another, or appear as clumps, it is sometimes possible to split off a single crystal by prodding the clump gently at the junction point between the crystals with a scalpel or a glass fibre.

5.1.1.1.3. *Polymorphism*

Intermolecular contacts between protein molecules in the crystalline state determine the mechanical stability of the crystal. If the conditions used for crystallization vary, the number and identity of these contacts may be changed, and polymorphs will result. Polymorphism is the existence of two or more crystalline forms of a given material. Polymorphs have different unit-cell dimensions and hence different molecular arrangements within them. This property is common for biological macromolecules and can be used to select the best crystalline form for X-ray diffraction studies. Different polymorphs of a particular material are often prepared by varying the crystallization conditions. They may also develop in the same crystallizing drop because supersaturation conditions may change while a crystal is growing. Examples of polymorphs are provided by hen egg-white lysozyme, which can form tetragonal, triclinic, monoclinic or orthorhombic crystals, depending on the pH, temperature and nature of added salts in the crystallization setup (Steinrauf, 1959; Ducruix & Giegé, 1992: Oki *et al.*, 1999).

A regular surface that offers a charge distribution pattern that is complementary to a possible protein layer in a crystal can sometimes be useful in producing a starting point for the nucleation of new protein crystals. Epitaxy is the oriented growth of one material on a crystal of an entirely different material. Regularities on the surface of the first crystal can act as a nucleus for the oriented growth of the second material. Generally, there should be similar, but not necessarily exactly matching, repeat distances in the two crystals. Epitaxy has been used with considerable success for the growth of protein crystals on selected mineral surfaces (McPherson & Shlichta, 1988). For example, lysozyme crystals grow well on the surface of the mineral apophyllite. Crystals of related macromolecules can also be used as nucleation sources for protein crystallization. Epitaxy can, however, sometimes be a nuisance rather than a benefit if the crystallization setup contains surfaces with unwanted regularity.

A change in the environment around a protein crystal may also cause a change in unit-cell dimensions, and possibly even in space group. For example, the transference of a RuBisCO crystal from a high-salt, low-pH mother liquor to a low-salt, high-pH synthetic mother liquor produced a more densely packed polymorph. The overall unit-cell dimensions were smaller in the latter (V_m changed from 3.16 to 2.74 $\text{Å}^3\ \text{Da}^{-1}$) (Zhang & Eisenberg, 1994).

5.1.1.1.4. *Twinning*

Twinning is a phenomenon that can cause much grief in X-ray diffraction data measurements. It has been described as 'a crystal growth anomaly in which the specimen is composed of separate crystal domains whose orientations differ in a specific way ... some or all of the lattice directions in the separate domains are parallel' (Yeates, 1997). Thus, a twin consists of two (or more) distinct but coalescent crystals. This effect has been described in terms of their diffraction patterns as follows: 'Some crystals show splitting of diffraction spots owing to the different tilts of the two lattices. Others pretend to be single crystals with no split spots, and their symmetries of intensity distribution vary with every data set. These latter have been called hemihedral, and in them the unique axes of the two crystals are exactly reversed parallel with each other.' (Igarashi *et al.*, 1997). Perfect hemihedral twinning (when there are equal proportions of each twin member) can be detected from the value of $\langle I^2\rangle/\langle I\rangle^2$ for the acentric data; it is near 2 for untwinned data and 1.5 for twinned data (Yeates, 1997).

Twinning may sometimes be prevented by introducing variations into the crystallization setup. Such changes could involve the pH or the nature of the buffer. Variations in the seeding technique used, or the introduction of additional agents, such as metal ions or salts, detergents, or certain amino acids, can also be tried. One method for estimating the degree of twinning is based on the fact that each measured X-ray diffraction intensity is the sum of the intensities from the two (or more) crystal lattices (suitably weighted according to the proportion in which each lattice alignment occurs in the crystal). The relative proportion of each component can therefore be estimated. Detwinned intensities obtained by this method should only be positive or zero (not negative) within experimental error (Stanley, 1972; Britton, 1972; Rees, 1980). Crystal structures of hemihedrally twinned crystals are now being determined (Gomis-Rüth *et al.*, 1995; Breyer *et al.*, 1999).

5.1.1.2. *Properties of crystal faces*

5.1.1.2.1. *Indexing crystal faces*

Crystal faces are described by three numbers, the Miller indices, that define the relative positions at which the three axes of the unit cell are intercepted by the crystal face (Blundell & Johnson, 1976; Phillips, 1957). The crystal face that is designated *hkl* makes intercepts $x = a/h$, $y = b/k$ and $z = c/l$ with the three axes (a, b and c) of the unit cell. When the Miller indices are negative, because the crystal face intercepts an axis in a negative direction, they are designated $-h - k - l$ or $\bar{h}\bar{k}\bar{l}$. Most faces of a crystal are, as required by the law of rational indices, represented by small integers. For symmetry reasons, planes in hexagonal crystals are conveniently described by four axes, three in a plane at 120° to each other. This leads to four indices, *hkil*, where $i = -(h + k)$. Crystal faces are designated by round brackets, *e.g.* (100), as shown in two simple examples in Fig. 5.1.1.1. A set of faces then defines a crystal form. All sets of planes *hkl* related by symmetry, such as the main faces of an octahedron (111), $(11\bar{1})$, $(1\bar{1}1)$, $(\bar{1}11)$, $(1\bar{1}\bar{1})$, $(\bar{1}1\bar{1})$, $(\bar{1}\bar{1}1)$ and $(\bar{1}\bar{1}\bar{1})$, may be represented by the use of curly brackets, *e.g.* {111}. Square brackets, *e.g.* [111], are used to indicate a direction in a crystal, [001] being the *c* axial direction. Thus, information about several faces of a crystal is contained in information about one face if the relevant symmetry of the crystal is known. If the atomic structure of the crystal is known, it is possible to determine which aspects of the macromolecule lie on the various crystal faces.

5.1.1.2.2. *Measurement of crystal habit*

The habit of a crystal may be described in detail by measurements, particularly of the angles between adjacent faces. This can be done with an optical goniometer, in which a collimated visible beam of light is reflected from different faces as the crystal is rotated, and the angles between positions of high light intensity are noted. Such studies can be combined with X-ray diffraction measurements of the crystal orientation of the unit cell with respect to the various crystal faces (Oki *et al.*, 1999).

5.1.1.3. *Optical properties*

Crystals interact with light in a manner which depends on the arrangement of atoms in the crystal structure, any symmetry in this arrangement and the chemical nature of the atoms involved. Refraction is seen as a change in the direction of a beam of light when it passes from one medium to another (such as the apparent bend in a pencil placed in a beaker of water). The refractive index is the ratio of the velocity of light in a vacuum to that in the material under investigation and is greater than unity. It is measured by the extent to which the direction of a beam of light changes on entering a medium.

If a protein crystal has grown in the cubic system, its refractive index will be the same in all directions and the crystal is described as optically isotropic. Most protein crystals, however, form crystals with anisotropic properties, that is, their properties vary with the direction of measurement of the crystal. For example, some crystals appear differently coloured when viewed in different directions, and are described as pleochroic. The absorption of light is greatest when light is vibrating along bonds of chromophoric groups in the molecules in the crystals rather than perpendicular to them, and therefore they show interesting effects in plane-polarized light (in which the electric vectors lie in one plane only) (Bunn, 1945; Wahlstrom, 1979).

Anisotropy of the refractive index of a protein crystal, that is, its birefringence, can be used by biochemists to determine whether or not a protein has been crystallized. If the protein preparation in a test tube is held up to the light and shaken, birefringent protein microcrystals are revealed by light streaks, a schlieren effect. This occurs because the crystals have a different refractive index from the bulk of the liquid. Birefringence implies that there is double refraction as light passes through a crystal, and the light is split into two components (the ordinary and extraordinary rays) that travel with different velocities and have different properties (those of the ordinary ray being normal). Iceland spar (calcite) provides the ideal example of double refraction. Birefringence is measured as the difference between the refractive indices for the ordinary and extraordinary rays, and a crystal is described as positively birefringent if the refractive index is greater for the extraordinary ray. If a crystal is positively birefringent ($n_E > n_O$), it can be assumed to contain rod-like bodies lying parallel to the single vibration direction of greatest refractive index (n_E). If a crystal is negatively birefringent ($n_O > n_E$), it can be assumed to contain plate-like bodies lying perpendicular to the single vibration direction of least refractive index (n_E). For example, in crystalline naphthalene, the highest refractive index is in the direction of the highest density of atoms, along the long axis of the molecule. Similar arguments can be applied to crystalline macromolecules, such as haemoglobin, which is strongly pleochroic, appearing dark red and opaque in two extinction directions, and light red and transparent in the third (Perutz, 1939). Thus, the coefficient of absorption is high when the electric vibration of plane-polarized light is parallel to the haem groups, but is low in other directions. Similarly, a specific carotenoid protein has been found to appear orange or clear depending on the orientation of the crystal relative to the direction of polarization of the light hitting it (Kerfeld *et al.*, 1997). The darkest orange colour, corresponding to a maximum absorbance of the carotenoid cofactor, is found when the polarizer is aligned along the *a* axis (the long axis of the crystals). This suggests that all the carotenoid cofactor molecules in this crystal structure lie nearly parallel to the *a* axis.

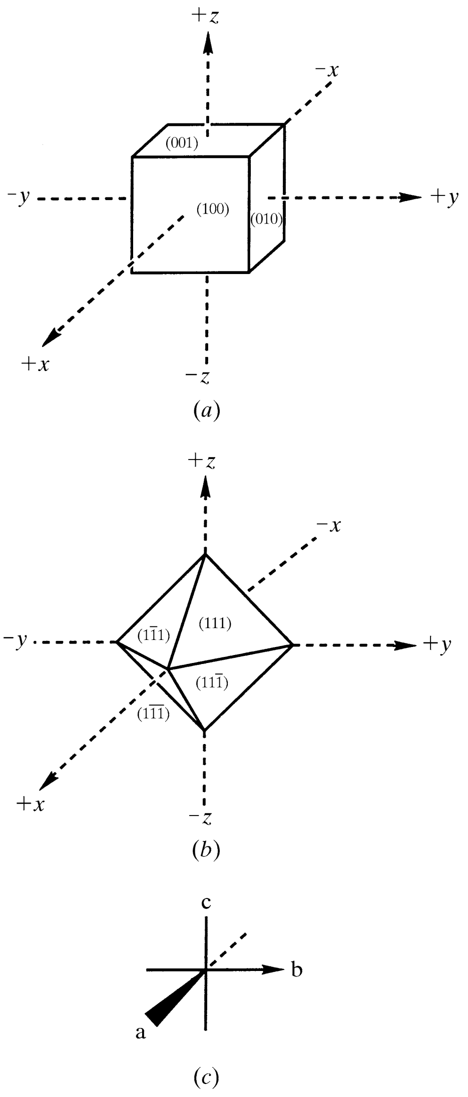

Figure 5.1.1.1
Crystal faces. (*a*) Cube and (*b*) octahedron. (*c*) Unit-cell axes.

The directions along which double refraction is observed can be used to give some information on the crystal class. Some crystals are found to have one, and only one, direction (the optic axis) along which there is no double refraction. Crystals with this property are called uniaxial. They have two principal refractive axes and are tetragonal, hexagonal or rhombohedral. Other crystals are found to have two directions along which there is no double refraction (two optic axes), and these are called biaxial. Such crystals are either orthorhombic, monoclinic or triclinic and have three principal refractive indices.

5.1.1.3.1. Crystals between crossed polarizers

Most protein crystals are birefringent and are brightly coloured in polarized light. In order to view these effects, crystals (in their mother liquor) are set on a microscope stage with a Nicol prism (polarizing material) between the light source and the microscope slide (the polarizer). Another Nicol prism is set between the crystal and the eyepiece (the analyser). The crystal should not be in a plastic container, since this would produce too many colours. If the vibration plane of the analyser is set perpendicular to that of the polarizer (to give 'crossed Nicols'), no light will pass through in the absence of crystals, and the background will be dark. If the crystal is isotropic, the image will remain dark as the crossed Nicol prisms are rotated. If, however, the crystal is birefringent (with two refractive indices), the crystal will appear coloured except at four rotation positions (90° apart) of the crossed Nicol prisms, where the crystal and background will be dark (extinguished). At these positions, the vibration directions of the Nicol prisms coincide with those of the crystal. If one is looking exactly down a symmetry axis of a crystal that is centrosymmetric in projection (such as a tetragonal or hexagonal crystal), the crystal will not appear birefringent, but dark. By noting the external morphology of the crystal with respect to its angle of rotation, one can often deduce the directions of the unit-cell axes in the crystal (Hartshorne & Stuart, 1960). Examination of a crystal under crossed Nicol prisms can also provide information on crystal quality. For example, sometimes the components of a twinned crystal extinguish plane-polarized light independently. Other methods of examining crystals include Raman spectroscopy (Kudryavtsev *et al.*, 1998).

5.1.1.3.2. Refractive indices and what they tell us about structure

The refractive index of a crystal can be measured by immersing it in a mixture of liquids of a known refractive index in which the crystal is insoluble. The liquid composition is then varied until the crystal appears invisible. At this point, the refractive indices of the crystal and the liquid are the same. If the refractive index is the same in all directions, the crystal is optically isotropic, but most protein crystals are optically anisotropic and have more than one refractive index. For example, tetragonal crystals have different refractive indices for light vibrating parallel to the fourfold axis and for light vibrating perpendicular to it. These refractive indices are measured by the use of plane-polarized light.

5.1.1.4. Packing of molecules in crystals

Growth kinetics of the different faces should be correlated with the structural anisotropy of the intermolecular contacts. It has been found that a judicious mutation of a single surface residue of a protein can markedly affect its solubility and hence crystallizability. This method has been used with great success for crystallizing a retroviral integrase (Dyda *et al.*, 1994).

The relationship between crystal morphology and internal crystal structure was examined in the mid-1950s (Hartman & Perdok, 1955*a*,*b*,*c*). It was shown that the morphology of a crystal is determined by 'chains' of strong intermolecular interactions (hydrogen bonding, van der Waals contacts, molecular stacking) running through the entire crystal. For a crystal to grow in the direction of a strong interaction ('bond'), these bonds must form an uninterrupted chain through the structure, giving rise to the periodic bond chain theory. The stronger the interaction between molecules, the more likely the crystal is to be elongated in that direction. If a bond chain contains interactions of different kinds, its influence on the shape of the crystal is determined by the weakest interaction present in a particular chain. Prominent faces are parallel to at least two high-energy bond chains. This enables a correlation to be made between the crystal lattice and the crystal morphology, based on the fact that direct protein–protein contacts, reinforced by well ordered solvent molecules, are important in determining crystal packing (Frey *et al.*, 1988). Studies of the morphology of tetragonal lysozyme (Nadarajah & Pusey, 1996; Nadarajah *et al.*, 1997) showed that the crystallizing unit is a helical tetramer (centred on the 4_3 crystallographic axes).

5.1.2. Crystal mounting

5.1.2.1. Introduction to crystal mounting

Once crystals have been obtained and visually characterized, the next procedure involves the transfer of a selected crystal to an appropriate mounting device so that the crystal may be characterized using X-rays. Macromolecular crystals are generally obtained from and stored in a solution containing the precipitant or precipitants and other substances such as uncrystallized protein or other macromolecules. The object is to mount the crystal in such a way that it is undamaged by cracking, drying out, dissolving *etc.* during this operation. In some cases, the crystal may have been stored in a solution containing volatile solvents. Alternatively, the crystals may have been grown at a temperature lower than room temperature and therefore may require special handling in order to avoid crystal deterioration. In other cases, it may be desirable to prepare the crystal for study at cryogenic temperatures. This section deals with the mounting of crystals for all these conditions and concentrates on the mounting of crystals for diffraction experiments at or just below room temperature. Procedures such as 'flash cooling' are used to reduce radiation damage. Crystal-mounting techniques for cryogenic experiments are covered in detail in Part 10 and are only mentioned briefly here. In general, the most difficult part of mounting macromolecular crystals is the transfer of the crystal from a holding solution to a suitable mount. A capillary or, if cryogenic experiments are to be carried out, a cryoloop should be used.

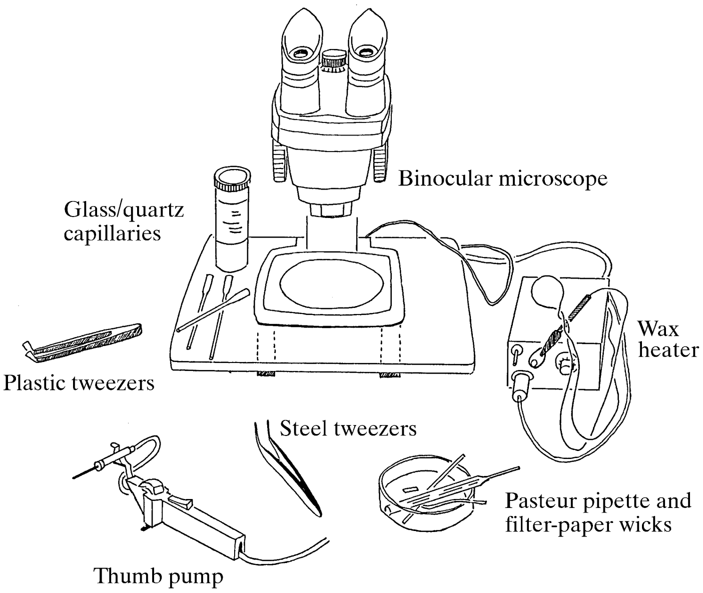

Figure 5.1.2.1
Tools commonly used for mounting crystals.

5.1.2.2. Tools for crystal mounting

In order to facilitate the process of mounting macromolecular crystals for X-ray diffraction experiments, it is necessary to have the appropriate tools for the task. Fig. 5.1.2.1 shows a collection of some useful tools for the mounting of crystals. These include a binocular microscope, tweezers (two types), thin glass capillaries, Pasteur pipettes, a heater, paper wicks, and a thumb pump. Other useful tools and supplies include surgical scissors, dental wax, latex tubing, light vacuum oil, a cryogenic mounting loop, Plasticine, mounting platforms, mounting pins, absorbent dental points and micropipettes with plastic tips. There are many other items that might be useful, and several variations are found in different laboratories. An important factor in the transfer of crystals from a holding solution to a capillary is that the experimenter needs to feel at ease with the process. The method that will be detailed here has evolved over time and has proved to be a relatively anxiety-free process. Other methods for crystal mounting may be found in the literature (Rayment, 1985; Sawyer & Turner, 1992; McRee, 1993). All of the methods outlined here and in the literature have the same goal, namely, the successful transfer of a macromolecular single crystal to a suitable mount for X-ray data collection.

5.1.2.2.1. *Microscope*

Perhaps the single most important piece of equipment for examining and mounting crystals is a binocular dissection microscope. This should have variable zoom capabilities, and there should be sufficient distance (*e.g.* 5–10 cm) between the objective lens of the microscope and the microscope stage to accommodate the necessary equipment and allow manipulation of the crystals and solutions. A magnification of between 10 and 40 times is probably best in practice. It is also important to ensure that the light source of the microscope is not so intense that it heats the microscope stage, thereby damaging the macromolecular crystals. If the microscope is fitted with crossed polarizers, the quality of the crystals can be assessed.

5.1.2.2.2. *Capillaries*

The capillaries used for crystal mounting are made of thin-walled glass. These capillaries range from 0.1 to 2.0 mm in diameter and have a stated wall thickness of 0.01 mm. In practice, however, the larger the diameter of the capillary, the thinner the glass wall. Therefore, handling of the larger-diameter capillaries is generally very difficult because they are so fragile. Capillaries made of fused quartz are also available, but are not recommended for general use because they produce a higher background with X-rays. Quartz capillaries are not as fragile as the thin-walled glass capillaries, however, and may be useful in experiments where the tensile strength of the capillary is important, for example, when a diffraction flow-cell experiment is planned (Petsko, 1985). In addition, small-diameter capillaries (produced in the laboratory by drawing out glass tubing or Pasteur pipettes) will be needed to aid in the removal of excess liquid around the crystal after the transfer from the crystallization dish to a capillary has been completed.

5.1.2.2.3. *Thumb pump*

The thumb pump is a simple micropipetting device for transferring very small amounts of liquid in a highly controlled manner, making it an extremely useful tool for directly transferring protein crystals from solution to capillary, thus minimizing the chance of crystal damage. This simple device allows the experimenter to have much more control over volume transfers than any other device we have tried. The mechanism is simple and easy to operate. The device shown in the illustration can be held and manipulated with one hand. The capillary is held firmly in place and the pipetting action is controlled by a thumb wheel (part of the thumb pump), which affords a great deal of control over the volume of liquid being transferred with the crystal.

5.1.2.2.4. *Heater*

The heater illustrated here consists of a variable rheostat and a heating element. The latter is a short piece of Nichrome wire which has been coiled and attached to the rheostat *via* wires that run through a ball-point pen barrel. This permits a fine temperature control for melting dental wax and for controlling where the heat is applied.

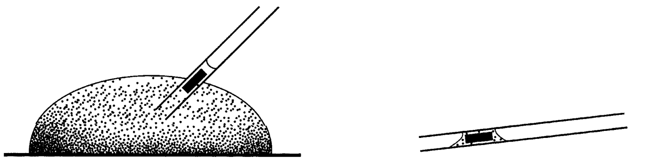
5.1.2.3. *Capillary mounting*

One must first select a capillary for mounting the crystal. A general rule to follow is to select a capillary that has a diameter that is approximately twice the size of the crystal dimension to be placed along the breadth of the capillary. Thus, to mount an elongated parallelepiped with the longest crystal dimension parallel to the capillary, it is necessary to take into account the cross section of the crystal perpendicular to the longest dimension. This rule is only a guide and is probably broken most of the time. Indeed, for ‘chunky’ crystals, it may be advantageous to use a capillary only slightly larger than the crystal so that the crystal may be in contact with the capillary wall in more than one place, thereby making the mount more stable. The object is to have enough of the crystal in contact with the capillary wall to allow the crystal to be held in place with a small amount of mother liquor. One possible problem that occurs with very thin crystals is that the crystal may bend to conform to the shape of the capillary wall. In this case, the crystal is rendered unsuitable for X-ray diffraction experiments.

The capillary is prepared by first removing the flame-sealed tip. This is done with surgical scissors or by pinching with surgical tweezers and then gently tapping the capillary tip against a smooth hard surface to remove the jagged edges which may have resulted from this cutting. The removal of the jagged edges at the broken end of the capillary will simplify the transfer of the crystal from the holding solution to the capillary. The large flared end of the capillary is left intact, and, at this time, a rubber transfer tube with a mouthpiece can be fitted over the flared end of the capillary. The capillary can then be rinsed with distilled deionized water, or it may even be desirable to treat the capillary with some other solution, such as EDTA, or perhaps with a solution identical to that surrounding the crystal. The rinse solution is gently drawn up into the capillary, and the solution is then blown out into a waste container. This can be accomplished fairly rapidly, and then the capillary can be dried by gently drawing air in through the capillary tip. Only the excess liquid should be removed at this point if the rinse solution contains salts.

The crystal must now be transferred to a capillary from the storage location, which may be a shallow well in a depression slide, a droplet on a cover slip, or perhaps a vial containing crystals. Direct transfer from a droplet on a cover slip or from a shallow well of a depression slide to the final capillary is possible, but can be complicated if several crystals are present in the drop. The easiest way to set up the final crystal transfer is to first remove it from the original drop or vial using a micropipette with a tip that has been enlarged so that it will accommodate the desired crystal. The crystal is then transferred together with a few microlitres of solution to a siliconized cover slip or depression well using the micropipette. It may even be easier to place 5–10 µl of solution on a siliconized cover slip or depression well and then use a cryoloop to capture the crystal and deposit it in the solution. The crystal can now be easily drawn up into the capillary with the aid of the thumb pump. It will be accompanied by a small column of mother liquor, and the thumb pump can be used to position the crystal with its liquid at the desired location in the capillary. The excess mother liquor can now be removed by using a capillary that is much smaller than the data-collection capillary, as well as smaller than the crystal. A final drying can be accomplished using appropriately sized filter-paper wicks or absorbent dental points. A very small amount of liquid should be left behind to keep the crystal moist and to ‘glue’ the crystal to the capillary wall *via* surface tension. A crystal that is too dry will probably deteriorate and be useless for diffraction experiments, while a crystal that has too much liquid can slip during data collection. On the other hand, moderate drying has been found, in certain cases, to give a crystal with improved diffraction.

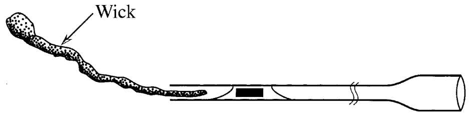
After the crystal is safely in position in the capillary, the capillary must be sealed in order to maintain the moisture necessary to prevent crystal deterioration. If desired, a short column of mother liquor may be placed in the capillary a few



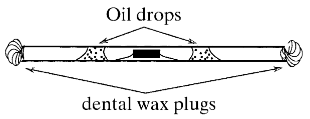
(*a*) Using the thumbwheel, draw the crystal into the capillary along with a short column of liquid

(*b*) Still using the thumbwheel, gently draw the crystal and mother liquor to the desired position in the capillary

(*c*) Using a small capillary, remove the excess mother liquor



(*d*) Remove liquid to desired dryness with a filter-paper wick



(*e*) Place columns of oil 4–5 mm from each end of the crystal and seal the ends of the capillary with dental wax

Figure 5.1.2.2
Mounting a crystal in a capillary.

millimetres away from the crystal. This is usually necessary if capillaries larger than 1 mm in diameter are used. A small strip of filter paper may also be placed in the capillary and then dampened with mother liquor. Both methods allow the moisture level in the crystal to be maintained. A reasonably good first seal may consist of a short column of light vacuum oil on both sides of the crystal, again, a few millimetres away from it. At this time, a ring of molten dental wax is placed along the capillary beyond the oil drop nearest the flared end of the capillary, and the capillary is then cut or broken just beyond the wax. The final seal may then be accomplished using molten dental wax or perhaps even epoxy at each end of the capillary. The diffraction equipment and arrangement will dictate the position of the crystal in the capillary, and this should be accommodated before the final seals are put in place. The geometry of the capillary could aid in preventing slippage of the wedged crystal during data collection (Åkervall & Strandberg, 1971). Alternatively, a specific crystal coating which effectively glues the crystal to the interior of the capillary can be used (Rayment *et al.*, 1977). The capillary with its crystal is now ready to be placed on the platform of choice for placement on the goniometer head in final preparation for diffraction experiments. Fig. 5.1.2.2 illustrates the steps in mounting a crystal in a capillary in preparation for the X-ray experiment.

The above method deals only with crystals which are to be mounted at or near room temperature for experiments at or near room temperature. An alternative approach is to grow a crystal in a capillary (Åkervall & Strandberg, 1971), which could eliminate the need to manipulate the crystal manually. When crystals have been grown in the presence of detergents or gels, specific methods may be required for mounting (McRee, 1993). The appropriate procedure for flash cooling of crystals is detailed in Part 10.

Chapter 5.2. Crystal-density measurements

E. M. Westbrook

5.2.1. Introduction

Crystal-density measurements have traditionally been a valuable and accurate (±4%) method for determining molecular weights of proteins (Crick, 1957; Coleman & Matthews, 1971; Matthews, 1985). But since exact chemical compositions of proteins being crystallized today are usually known from DNA sequences, crystal densities are rarely used for this purpose. Rather, crystal-density measurements may be necessary to define a crystal's molecular-packing arrangement, particularly when a crystal has an unusual packing density (very dense or very open); when there are a large number of subunits in the crystallographic asymmetric unit; when the structure consists of heterogeneous subunits, so the molecular symmetry or packing is uncertain; and for crystals of nucleic acids, nucleic acid/protein complexes and viruses.

5.2.2. Solvent in macromolecular crystals

Crystals of biological macromolecules differ from crystals of smaller molecules in that a significant fraction of their volume is occupied by solvent (Adair & Adair, 1936; Perutz, 1946; Crick, 1957). This solvent is not homogeneous: a part binds tightly to the macromolecule as a hydration shell, and the remainder remains free, indistinguishable from the solvent surrounding the crystal.

Hydration is essential for macromolecular stability: bound solvent is part of the complete macromolecule's structure (Tanford, 1961). Diffraction-based studies of macromolecular crystals verify the presence of well defined bound solvent. Typically, 8–10% of the atomic coordinates in each Protein Data Bank file are those of bound water molecules. The consensus observation of protein hydration (Adair & Adair, 1936; Perutz, 1946; Edsall, 1953; Coleman & Matthews, 1971; Kuntz & Kaufmann, 1974; Scanlon & Eisenberg, 1975) is that every gram of dry protein is hydrated by 0.2–0.3 g of water: this is consistent both with the presence of a shell of hydration, the thickness of which is about one water molecule (2.5–3 Å), and with the rule-of-thumb that approximately one water molecule is found for every amino-acid residue in the protein's crystal structure. Matthews (1974) suggests setting this hydration ratio, w, to 0.25 g water per gram of protein as a reasonable estimate for typical protein crystals.

Crystallographic structures also exhibit empty regions of 'free' solvent. Such voids are to be expected: closely packed spheres occlude just 74% of the space they occupy, so to the extent that proteins are spherical, tight packing in their crystals would leave 26% of the crystal volume for free solvent. Although the distinction between free and bound solvent is not sharp (solvent-binding-site occupancies vary, as do their refined B factors), it is a useful convention and is consistent with many observed physical properties of these crystals.

5.2.3. Matthews number

In an initial survey of 116 crystals of globular proteins (Matthews, 1968) and in a subsequent survey of 226 protein crystals (Matthews, 1977), Matthews observed that proteins typically occupy between 22 and 70% of their crystal volumes, with a mean value of 51%, although extreme cases exist, such as tropomyosin, whose crystals are 95% solvent (Phillips *et al.*, 1979). The volume fraction occupied by a macromolecule, φ_m, is reciprocally related to V_M, the Matthews number, according to

$$V_M = \overline{v}_m / N_o \varphi_m = V/nM, \tag{5.2.3.1}$$

where $\overline{v}_m$ is the partial specific volume of the macromolecule (Tanford, 1961), N_o is Avogadro's number, V is the volume of the crystal's unit cell, n is the number of copies of the molecule within the unit cell and M is the molar weight of the macromolecule (grams per mole). V_M is the ratio between the unit-cell volume and the molecular weight of protein contained in that cell. The distribution of V_M (2.4 ± 0.5 Å^3 Da^{-1}) is asymmetric, being sharply bounded at 1.7 Å^3 Da^{-1}, a density limit consistent with spherical close packing. The upper limits to V_M are much less distinct, particularly for larger proteins. Matthews observed a slight tendency for V_M to increase as the molecular weight of proteins increases. V_M values below 1.9, or above 2.9, can occur but are relatively rare (beyond a 1σ cutoff).

The unit-cell volume, V, is determined from crystal diffraction. The partial specific volume of a macromolecule, $\overline{v}_m$, is the rate of change in the volume of a solution as the (unhydrated) macromolecule is added. It can be measured in several ways, including by ultracentrifugation (Edelstein & Schachman, 1973) and by measuring the vibrational frequency of a capillary containing a solution of the macromolecule (Kratky *et al.*, 1973). $\overline{v}_m$ typically has a value around 0.74 cm^3 g^{-1} for proteins and around 0.50 cm^3 g^{-1} for nucleic acids (Cantor & Schimmel, 1980). Values of $\overline{v}_m$ are tabulated for all amino acids and nucleotides, and $\overline{v}_m$ of a macromolecule can be estimated with reasonable accuracy as the mean value of its monomers. Commercial density-measuring instruments are available to determine $\overline{v}_m$ by the Kratky method. Because M is usually well known from sequence studies, n – the number of copies of the macromolecule in the unit cell – can be calculated thus:

$$n = V/V_M M = V N_o \varphi_m / \overline{v}_m M. \tag{5.2.3.2}$$

For proteins, evaluating this expression with $V_M = 2.4$ usually provides an unambiguous integer value for n – which must be a multiple of the number of general positions in the crystal's space group! Setting n to its integer value then provides the actual value for V_M. If the calculated V_M value lies beyond the usual distribution limits, if n has an unexpected value or a large value, or if the crystal contains unusual components or several different kinds of molecular subunits, the crystal density may need to be measured accurately.

5.2.4. Algebraic concepts

Let V be the volume of one unit cell of the crystal. Let m_c be the total mass within one unit cell, and m_m, m_{bs} and m_{fs} be the masses, within one unit cell, of the macromolecule, bound solvent and free solvent, respectively. Let ρ_c, ρ_m, ρ_{bs} and ρ_{fs}, respectively, be the densities of a complete macromolecular crystal, its unsolvated macromolecule, its bound-solvent compartment and its free-solvent compartment. Let φ_m, φ_{bs} and φ_{fs}, respectively, be the

Copyright © 2012 International Union of Crystallography

fractions of the crystal volume occupied by the unsolvated macromolecule, the bound solvent and the free solvent. By conservation of mass,

$$m_c = m_m + m_{bs} + m_{fs}. \tag{5.2.4.1}$$

The volume fractions must all add to unity:

$$\varphi_m + \varphi_{bs} + \varphi_{fs} = 1. \tag{5.2.4.2}$$

The density of the crystal is the total mass divided by the unit-cell volume:

$$\rho_c = \frac{m_c}{V} = \frac{m_m}{V} + \frac{m_{bs}}{V} + \frac{m_{fs}}{V}. \tag{5.2.4.3}$$

The mass in each solvent compartment is the product of its density and the volume it occupies:

$$m_{bs} = \rho_{bs} V \varphi_{bs}, \qquad m_{fs} = \rho_{fs} V \varphi_{fs}. \tag{5.2.4.4}$$

The mass of the macromolecule in the cell can be defined either from its partial specific volume, $\overline{\upsilon}_m$, the unit-cell volume, V, and the molecules' volume fraction, φ_m, or from the molar weight, M, the number of molecular copies in the unit cell, n, and Avogadro's number, N_o:

$$m_m = V\varphi_m/\overline{\upsilon}_m = nM/N_o. \tag{5.2.4.5}$$

Now (5.2.4.3) may be rewritten as

$$\rho_c = \varphi_m/\overline{\upsilon}_m + \rho_{bs}\varphi_{bs} + \rho_{fs}\varphi_{fs}. \tag{5.2.4.6}$$

Define a mean solvent density, ρ_s:

$$\rho_s = \frac{\rho_{bs}\varphi_{bs} + \rho_{fs}\varphi_{fs}}{\varphi_{bs} + \varphi_{fs}}. \tag{5.2.4.7}$$

This allows (5.2.4.6) to be rewritten as

$$\rho_c = \varphi_m/\overline{\upsilon}_m + (1 - \varphi_m)\rho_s. \tag{5.2.4.8}$$

Upon rearrangement, this gives expressions for the volume fraction of a macromolecule and for the molecular-packing number:

$$\begin{aligned} \varphi_m &= \frac{\rho_c - \rho_s}{(\overline{\upsilon}_m)^{-1} - \rho_s} = \frac{n\overline{\upsilon}_m M}{VN_o}, \\ n &= \frac{VN_o}{\overline{\upsilon}_m M}\frac{\rho_c - \rho_s}{(\overline{\upsilon}_m)^{-1} - \rho_s}. \end{aligned} \tag{5.2.4.9}$$

In (5.2.4.9), all terms can be measured directly, except ρ_s. The treatment of ρ_s will be discussed in Section 5.2.7. (5.2.4.9) defines the total macromolecular mass in the unit cell, $m_m = nM/N_o$, from a measurement of the crystal density ρ_c. If M were known from the primary sequence of the molecule, this measurement determines the molecular-packing number, n, with considerable certainty. If the molar weight were not accurately known, it could be determined by measuring the crystal density.

5.2.5. Experimental estimation of hydration

During refinement of crystal structures, crystallographers must decide how many solvent molecules are actually bound to the macromolecule and for which refined coordinates are meaningful. The weight fraction of bound solvent to macromolecule in the crystal, w, is estimated for most protein crystals to be about 0.25 (Matthews, 1974, 1985). However, its true value can be derived experimentally in the following manner. Since all relevant studies identify the bound solvent as water, it is reasonable to set the density of bound solvent as $\rho_{bs} = 1.0$ g ml^{-1}. Therefore, w can be expressed algebraically as

$$w = \frac{m_{bs}}{m_m} = \frac{\varphi_{bs}\rho_{bs}\overline{\upsilon}_m}{\varphi_m} = \frac{\varphi_{bs}\overline{\upsilon}_m}{\varphi_m}. \tag{5.2.5.1}$$

For crystals in which the rules-of-thumb $w = 0.25$ and $\overline{\upsilon}_m = 0.74$ cm^3 g^{-1} are valid, (5.2.5.1) implies that bound solvent occupies about one-third of the volume occupied by protein.

The crystal density, ρ_c, changes linearly with the density of free solvent surrounding the crystal. Let ρ_o be defined as the density the crystal would have if all its solvent were pure water ($\rho_s = 1.0$ g ml^{-1}):

$$\rho_o = 1 + \varphi_m(1/\overline{\upsilon}_m - 1). \tag{5.2.5.2}$$

A plot of crystal density against density of the supernatant (free solvent) solution should be a straight line with an intercept (at $\rho_{fs} = 1.0$ g ml^{-1}) of ρ_o and a slope of φ_{fs}. Therefore, by making a few crystal-density measurements, each with the crystal first equilibrated in solutions of varying densities, experimental values for ρ_o and φ_{fs} can be derived. If the partial specific volume is known for this molecule, φ_m, φ_{bs} and w can be derived from the expressions above. This approach was used by Coleman & Matthews (1971) and Matthews (1974) to measure molecular weights of six crystalline proteins, assuming $w = 0.25$, but their measurements could alternatively have assigned more accurate values to w, had the molecular weights been previously known. Scanlon & Eisenberg (1975) measured w for four protein crystals by this method (values betwen 0.13 and 0.27 were observed) and also confirmed that bound solvent exhibited a density of 1.0 g ml^{-1}.

5.2.6. Methods for measuring crystal density

Density measurements of macromolecular crystals are complicated by their delicate constitution. These crystals tolerate neither dehydration nor thermal or physical shock or stress. Furthermore, since macromolecular crystals contain free solvent, their densities will change as the density of the solvent in which they are suspended is changed. They cannot be picked up with tweezers, nor rinsed with arbitrary solvents, nor placed out to dry on the table.

The other experimental problem with these crystals is that they are very small. Typically, their linear dimensions are 0.1–0.2 mm, volumes are 1–10 nl and weights are 1–10 µg. Molecular structures can now be determined from even smaller crystals (linear dimensions as small as 20 µm) using synchrotron radiation, so density-measurement methods compatible with very small crystals are required. With such small samples, it is far easier and more accurate to measure *densities* than to measure directly *volumes* and *weights*.

The physical properties of macromolecular crystals constrain the methods by which their densities can be measured accurately. In all circumstances, great care must be taken to avoid artifacts such as air bubbles or particulate matter which often adhere to these crystals. All measurements should be made at one tightly controlled temperature, since thermal expansion can change densities and thermal convection can corrupt density gradients. Because crystals contain solvent, it is bad to dry them, since this process usually disrupts them, changing all parameters in unpredictable ways. Yet many density-measurement methods require that all external solvent first be removed from the crystals, since the measured densities will be some average of crystal and any remaining solvent. This can be an almost insurmountable problem for crystals containing cavities and voids. Unfortunately, many crystallization mother liquors are viscous and difficult to remove, for example if they contain polyethylene glycol (PEG).

Richards & Lindley in Chapter 3.2 of *IT* C (2004) list six methods for measuring crystal densities: pycnometry, the method of Archimedes, volumenometry, the immersion microbalance, flotation and the gradient tube. The first three methods require direct weighing of the crystal and are therefore of limited value for crystals as small as those used in macromolecular diffraction, although these methods are used in various applications, such as mineralogy and the sugar industry. The latter three methods measure densities and density differences, and can therefore be used in macromolecular crystallography. A new method specifically for protein crystals has recently been described (Kiefersauer *et al.*, 1996), involving direct tomographic measurement of crystal volumes coupled with quantitative amino-acid analysis. Because the gradient-tube method remains the method of choice for most crystal-density measurements, it will be discussed last and most thoroughly here.

5.2.6.1. *Pycnometry*

Pycnometry measures the density of a liquid by weighing a calibrated volumetric flask before and after it is filled with the liquid. To measure a crystal's density, the pycnometer is first calibrated and weighed, and then the crystal sample, from which all external liquid has been removed, is introduced. The pycnometer is now reweighed, thus determining the crystal's weight. Next, liquid of known density is added, and the pycnometer is reweighed. The crystal volume is derived from the difference in volumes of the pycnometer with and without the crystal present. The method requires direct measurement of the crystal's weight, yet it is difficult to make microbalances with sensitivity and accuracy limits better than about 0.01 mg. Micropycnometry methods have been developed to determine mineral densities with as little as 5 mg of material (Syromyatnikov, 1935), but typical macromolecular crystals are 1000 times smaller than that.

5.2.6.2. *Volumenometry*

This technique measures the increase in gas pressure due to changes in the volume of a calibrated container into which the crystal, having previously been weighed, is introduced (Reilly & Rae, 1954). Almost any gas can be used for this technique if it is compatible with the apparatus and does not interact with the crystal. The empty, calibrated chamber is pressurized by adding a measured gas bolus, and this pressure is measured. After it is weighed, the crystal sample is placed in the container, which is repressurized by adding the same volume of gas. The difference in pressures between the two measurements is due to the change in volume of the container due to the crystal's presence. In principle, this method is compatible with powdered crystal samples, multiple crystals, or irregularly shaped crystals. As with micropycnometry, this technique is not appropriate for macromolecular crystals. The crystal must be free of external solvent, yet not dried, and the microbalance must be able to measure the crystal's weight precisely and accurately. The useful lower limit of crystal size for this technique, reported by Richards & Lindley in Chapter 3.2 of *IT* C (2004), is 0.01 ml.

5.2.6.3. *The method of Archimedes*

Known for thousands of years, this method measures the difference in weight of an object in air and in a liquid of known density. The difference divided by the liquid density gives the object's volume. The crystal is suspended by a vertical fibre or wire from a microbalance as it is dipped into the liquid. The surface tension of the liquid acting on the supporting fibre must be accounted for and corrected. The accuracy of this method improves as the density of the liquid used approaches that of the crystal. This method has been used with crystals as small as 25 mg (Berman, 1939; Graubner, 1986), but it does not lend itself well to density measurements of objects as small as macromolecular crystals.

5.2.6.4. *Immersion microbalance*

Barbara Low and Fred Richards developed this ingenious method, which permits the crystal to be weighed in a liquid environment. A microbalance (consisting of a thin horizontal quartz fibre, free at one end) is kept entirely within the liquid bath. Its vertical deflection, observed with a microscope, is initially calibrated as a function of weight (Low & Richards, 1952*b*; Richards, 1954). The density of the liquid can be determined with high precision by standard techniques. Each crystal's volume (in the 1952–1954 studies) was calculated from two orthogonal photomicrographs (this required that the crystal morphology be regular). The crystal density can then be calculated:

$$\rho_c = \rho_{\rm liquid} + \frac{\text{apparent crystal weight}}{\text{crystal volume}}. \qquad (5.2.6.1)$$

The easiest and most accurate part of the method is measuring the liquid density. Therefore, experimental error in determining crystal weight and volume can be minimized by using a liquid with a density close to that of the crystal. In the limit where the crystal and liquid densities are the same, this method is equivalent to the flotation method – the fibre deflection is zero and the accuracy of the crystal-density measurement should be high. As originally implemented, the method is useful only for crystals with simple shapes, for which orthogonal photomicrographs can yield good estimates for the volume. Perhaps the method might be generalized if the tomographic volume-measuring method were adopted, as described by Kiefersauer *et al.* (1996). Richards & Lindley in Chapter 3.2 of *IT* C (2004) state that the method is only suitable for large crystals (volumes of 0.1 mm^3 or greater).

5.2.6.5. *Flotation*

The crystal must first be wiped completely free of external liquid and then immersed in a mixture of organic solvents, the density of which is adjusted (by addition of denser or lighter solvents) until the crystal neither rises nor sinks. Note that if the liquid used were aqueous, the crystal density would change as the surrounding liquid density is changed (*e.g.* by adding salt), since the crystal's free-solvent compartment would exchange with the external liquid. In this case, the equilibrium density, ρ_e, is a function only of the hydration number, w, and the macromolecule's partial specific volume, $\overline{v}_m$:

$$\rho_e = (w + 1)/(w + \overline{v}_m). \qquad (5.2.6.2)$$

ρ_e is about 1.25 g ml^{-1} for all protein crystals, regardless of packing arrangements or molecular weights, since $w \simeq 0.25$ and $\overline{v}_m \simeq 0.74$ cm^3 g^{-1}.

When the crystal just floats, the liquid's density (which now equals the crystal density) can be measured by standard techniques with high accuracy. Flotation measurements can be made with small samples (Bernal & Crowfoot, 1934) and with slurries of microcrystals. Centrifugation should be used to accelerate the crystal settling rate each time the liquid density is altered. The

Table 5.2.6.1
Organic liquids for density determinations

Name	Density (g ml^{-1})
Carbon tetrachloride (tetrachloromethane), CCl_4	1.5940
Bromobenzene, CH_5Br	1.4950
Chloroform (trichloromethane), $CHCl_3$	1.4832
Methylene chloride (dichloromethane), CH_2Cl_2	1.3266
Chlorobenzene, CH_5Cl	1.1058
Benzene, CH_6	0.8765
m-Xylene, 1,3-$(CH_3)_2C_6H_4$	0.8642
Iso-octane (2-methylheptane), $C_5H_{11}CH(CH_3)_2$	0.6980

Table 5.2.6.2
Inorganic salts for density determinations

The densities are approximate values for aqueous solutions at 20 °C.

Solute	Density (g ml^{-1})
Sodium chloride	1.20
Potassium tartrate	1.40
Potassium iodide	1.63
Iron(III) sulfate	1.80
Zinc bromide	2.00
Zinc iodide	2.39

method can be tedious, so its practitioners rarely achieve an accuracy better than 0.2–1.0% (Low & Richards, 1952*a*).

5.2.6.6. *Tomographic crystal-volume measurement*

Recently, a new method for density measurement which is specific for protein crystals has been reported (Kiefersauer *et al.*, 1996). The crystal volume is calculated tomographically from a set of optical-shadow back projections of the crystal, with the crystal in many (>30) orientations. This measurement is analogous to methods used in electron microscopy (Russ, 1990). The crystal is mounted on a thin fibre which is in turn mounted on a goniostat capable of positioning it in many angular orientations. The crystal must remain bathed in a humidity-regulated air stream to avoid drying. The uncertainty of the volume measurement improves asymptotically as the number of orientations increases (estimated to be 10–15%). The images are captured by a digital charge-coupled device camera, transferred to a computer and processed with the program package *EM* (Hegerl & Altbauer, 1982). This same crystal must then be recovered and subjected to quantitative amino-acid analysis (the authors used a Beckman 6300 amino-acid analyser). With a lower limit of 100 pmol for each amino acid, the uncertainty of this measurement was estimated to be 10–20% for typical protein crystals. The method appears to work for crystals with volumes ranging between 4–50 nl. Errors in the determined values of n ranged from 4–30%.

Implementation of the method requires complex equipment and considerable commitment (in terms of hardware and software) by the research laboratory. The accuracy of the method is sufficient to determine n unambiguously in many cases, but it is not as high as can be obtained with gradient-tube or flotation methods if care is taken. The method has the virtue that once established in a research laboratory, it might lend itself to a considerable degree of automation, thereby reducing the activation barrier to measuring crystal densities for members of the research group.

5.2.6.7. *Gradient-tube method*

This is the most commonly used method for measuring densities of macromolecular crystals. It is simple and inexpensive to implement. It can be used to measure densities of very small crystals and crystalline powders. Practised with care, the gradient-tube method is capable of measuring crystal densities with a precision and accuracy of ±0.002 g ml^{-1}.

Although density gradients were used earlier for other purposes, the application of the gradient-tube method for crystal-density measurement was first described by Low & Richards (1952*a*). The gradient can be formed in a long glass column (preferably with volume markings, such as a graduated cylinder), in which case the crystal sample will settle by gravity in the tube; or in a transparent centrifuge tube, in which case the crystal's approach to its equilibrium density may be accelerated by centrifugation. The gradient may be made by two organic liquids (Table 5.2.6.1) with different densities, or it may be made by a salt concentration gradient in water (Table 5.2.6.2). In either case, formation of the gradient is simplified with a standard double-chamber 'gradient maker' – however, a *glass* gradient maker should be used if the gradient is made of organic solvents! Be aware that all these substances are toxic, particularly to the liver, and some are listed as carcinogens, so avoid prolonged exposure.

Desired upper and lower density limits for the gradient can be made by mixing two of these liquids in appropriate ratios. The sensitivity and resolution of the measurement can be enhanced by using a shallow gradient covering the expected density. These organic liquids have a nontrivial capacity to dessicate the crystal sample, so it is important that they be water-saturated before use. Also, when an alcohol is the precipitant of a crystal, organic solutions may be inappropriate for density measurements.

For aqueous gradients, the salts listed in Table 5.2.6.2 may be added to water to create a dense liquid.

A widely used variant of the method has been to form aqueous gradients with Ficoll, a sucrose polymer cross-linked with epichlorhydrin (Westbrook, 1976, 1985; Bode & Schirmer, 1985). Manufactured by the Pharmacia Corporation specifically for making density gradients used in the separation of intracellular organelles or intact cells, Ficoll is a large polymer ($M_r = 400\ 000$) which is very hydrophilic and soluble, and has chemical properties similar to sucrose. Since it is highly cross-linked, each Ficoll molecule tends to be globular and is so large that it is effectively excluded from the crystal. Ficoll precipitates protein from solution on a per-weight basis as effectively as polyethylene glycol and can prevent protein crystals from dissolving, even in the absence of other solutes. A 60% (w/w) solution of Ficoll has a density of about 1.26 g ml^{-1}, sufficiently dense that almost all protein crystals will float in this solution (nucleic acid crystals are usually too dense for Ficoll). Used with care (see below), Ficoll gradients seem to yield the most reproducible crystal-density measurements. Concentrated Ficoll solutions are quite viscous, so these gradients are usually made by manually overlaying small volumes (0.5 ml each) of decreasing density, rather than with a gradient maker. In a standard cellulose nitrate centrifuge tube of about 5 ml capacity, this procedure makes an almost continuous gradient which works satisfactorily.

The density column must be calibrated once it has been formed. This is performed by introducing small items of known density into the column and noting their vertical positions. The density of the gradient as a function of vertical position can then be defined by interpolating between adjacent calibrated points. Usually, the calibrating points are made from small drops of immiscible liquid. Thus, in an organic solvent gradient, the drops are made of salt water; in an aqueous gradient, the drops are made of mixed organics (previously saturated with water). To make each calibration drop, a solution is made up with approximately the desired density, and its exact density (± 0.002 g ml^{-1}) is measured pycnometrically or by refractive index (Midgley, 1951). The drops can be inserted into the gradient with a flame-narrowed Pasteur pipette (this takes practice). Once calibrated, these gradients tend to be extremely stable over many months.

With an organic liquid gradient, two methods have been used to introduce the crystal sample to be measured. It can be extracted from its mother liquor with a pipette and extruded onto filter paper, which wicks away all exterior aqueous liquid. When free of moisture, but before it dessicates, the crystal must be shaken, flipped, or scraped onto the gradient top surface and allowed to sink to its equilibrium position. The second method involves injection of the crystal sample, in an aqueous droplet, into the gradient solution with a Pasteur pipette. A very thin syringe (home-made or commercial) is then used to draw off all extraneous liquid, while the crystal remains submerged in the organic liquid. Either method requires considerable manual dexterity and practice, especially with very small crystals. A significant advantage of Ficoll and aqueous salt gradients is that the crystal does not need to be manipulated at all: any liquid surrounding the crystal, which was introduced into the gradient at the start, rapidly dilutes into the aqueous solution and does not appear to interfere with further measurements.

With very small crystals, the approach to equilibrium is so slow that it is wise to use centrifugation, especially if it is suspected that the density is changing with time (see below). Nitrocellulose centrifuge tubes compatible with swinging-bucket rotors are typically 1 cm diameter, 5 cm long cylinders and are suitably transparent for this work. Centrifugation at 2500–5000 r.p.m. for as little as five minutes is sufficient for most crystals to reach a stable position in the gradient. It can be difficult to find the crystal after centrifugation, so the one or two most likely density values should be calculated in advance, and looked for first. The positions of calibration drops and of crystals in these centrifuge tubes can be measured with a hand-held ruler to a resolution of about 0.5 mm.

Particularly for crystals with high values of V_M (*i.e.*, loosely packed) or for crystals of large molecular weight proteins, the apparent crystal density may increase with time: the crystal continues to sink and there is no apparent equilibrium spot. This behaviour is seen in both organic solvent gradients and Ficoll gradients, and the reasons for it are unclear. It may be that, in organic solvent gradients, some of the solvent can dissolve into the crystal; or the crystal may condense from slow dessication. In Ficoll gradients, it may be that sucrose monomers or dimers are present, which diffuse into the crystal over time. A careful study of this behaviour (Bode & Schirmer, 1985) in Ficoll gradients suggested that useful density values can still be obtained for these crystals by fitting the apparent density to an exponential curve:

$$\rho_c(t) = a + b\exp(-\lambda t). \qquad (5.2.6.3)$$

In this expression, parameters a, b and λ must be derived from the fitted curve. The crystals were inserted into the gradient with flame-narrowed Pasteur pipettes. Each crystal was initially surrounded by a small amount of mother liquor, which rapidly diffused into the Ficoll solution. Time zero was assigned as the time when centrifugation first began. It was necessary to observe crystal positions within the first minute, and at two- to five-minute intervals thereafter, to obtain a reasonable time curve for the density function. The experimental goal in the Bode & Schirmer experiment was to obtain a good estimate for the density value at time zero, $\rho_c(0) = a + b$. This was realized in all six of the crystal forms that manifested time-dependent density drift in the study.

5.2.7. How to handle the solvent density

It is necessary to have an accurate estimate of the mean solvent density, ρ_s, in (5.2.4.9). The Ficoll gradient-tube method is particularly convenient for this reason: the gradient can be made without any significant solute other than Ficoll. Since the free-solvent compartment of the crystal is entirely water, $\rho_s = \rho_{bs} = \rho_{fs} = 1.0$ g ml^{-1}. Therefore, in Ficoll density gradients, the crystal density becomes ρ_o, as defined in (5.2.5.2), and the packing number n can be calculated from

$$n = \frac{VN_o}{M}\frac{(\rho_c - 1)}{(1 - \overline{v}_m)}. \qquad (5.2.7.1)$$

Another way to set $\rho_s = 1.0$ g ml^{-1} is to cross-link the crystals with glutaraldehyde (Quiocho & Richards, 1964; Cornick *et al.*, 1973; Matthews, 1985), making the crystals insoluble even in the absence of stabilizing solutes. Once cross-linked, crystals can be transferred to a water solution prior to the density measurement, thereby substituting water for its free solvent. Care must be taken with cross-linking, however. Overnight soaking in 2% glutaraldehyde solutions can substantially increase the crystal density, while destroying its crystalline order (Matthews, 1985). Even 0.5% glutaraldehyde concentrations may change the observed density of some crystals if the exposure is for many hours – which may be necessary to render the crystal completely insoluble. Therefore, the densities observed from cross-linked crystals should be regarded with caution.

If it is necessary to carry out density measurements in an organic solvent gradient, then it is necessary in general to measure the crystal density at more than one free solvent density, since the relative volume fractions of the crystal's components are not known *a priori*. However, if this is a well behaved protein crystal, by setting $\overline{v}_m = 0.74$ ml g^{-1}, $V_M = 2.4$ Å^3 Da^{-1} and $w = 0.25$ g bound water per g protein, one can guess the crystal's volume compartments to be:

$$\varphi_m = 0.51, \qquad \varphi_{fs} = 0.32, \qquad \varphi_{bs} = 0.17,$$

and the mean solvent density to use in (5.2.4.9) would be

$$\rho_s \simeq 0.35 + 0.65\rho_{fs}. \qquad (5.2.7.2)$$

This may give reasonably reliable derivations for n in (5.2.4.9), with just one crystal-density measurement. Over-reliance on parameter estimates, however, can lead to bogus results, and (5.2.7.2) should be used with caution.

This work was supported by the US Department of Energy, Office of Biological and Environmental Research, under contract W31-109-ENG-38.

PART 6. RADIATION SOURCES AND OPTICS

Chapter 6.1. X-ray sources

U. W. Arndt

6.1.1. Overview

In this chapter we shall discuss the production of the most suitable X-ray beams for data collection from single crystals of macromolecules. This subject covers the generation of X-rays and the conditioning or selection of the X-ray beam that falls on the sample with regard to intensity, cross section, degree of parallelism and spectral composition. The conclusions drawn do not necessarily apply to smaller-unit-cell crystals or to noncrystalline samples.

6.1.2. Generation of X-rays

X-rays are generated by the interaction of charged particles with an electromagnetic field. There are four sources of interest to the crystallographer.

(1) The bombardment of a target by electrons in a vacuum tube produces a continuous ('white') X-ray spectrum, called *Bremsstrahlung*, which is accompanied by a number of discrete spectral lines characteristic of the target material. The most common target material is copper, and the most frequently employed X-ray line is the copper $K\alpha$ doublet with a mean wavelength of 1.542 Å. X-ray tubes are described in some detail in Chapter 4.2 of *IT* C (2004). We shall consider only the most important points in X-ray tube design here.

(2) Synchrotron radiation is produced by relativistic electrons in orbital motion. This is the subject of Part 8.

(3) The decay of natural or artificial radioisotopes is often accompanied by the emission of X-rays. Radioactive sources are often used for the testing and calibration of X-ray detectors. For our purposes, the most important source is made from ^{55}Fe, which has a half-life of 2.6 years and produces Mn $K\alpha$ X-rays with an energy of 5.90 keV.

(4) Ultra-short pulses of X-rays are generated in plasmas produced by the bombardment of targets by high-intensity sub-picosecond laser pulses (*e.g.* Forsyth & Frankel, 1984). In earlier work, the maximum pulse repetition frequency was much less than 1 Hz, but picosecond pulses at more than 1 Hz are now being achieved with µm-size sources. The time-averaged X-ray intensities from these sources are very low, so their application will probably remain limited to time-resolved studies (Kleffer *et al.*, 1993).

X-rays also arise in the form of channelling radiation resulting from the bombardment of crystals, such as diamonds, by electrons with energies of several MeV from a linear accelerator (Genz *et al.*, 1990) and in the form of transition radiation when multiple-foil targets are bombarded by electrons in the range 100–500 MeV (*e.g.* Piestrup *et al.*, 1991). It will be some time before these new sources can compete with the older methods for routine data collection.

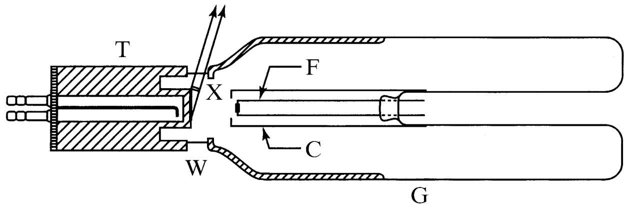

Figure 6.1.2.1
Section through a sealed X-ray tube. G, glass envelope; F, filament leads (at negative high voltage); C, focusing cup; T, target (at ground potential); W, one of four beryllium windows. The electron beam forms a line on the target, which is viewed at a small take-off angle to form a foreshortened effective source X.

6.1.2.1. Stationary-target X-ray tubes

A section through a permanently evacuated, sealed X-ray tube is shown in Fig. 6.1.2.1 The tube has a spirally wound tungsten filament, F, placed immediately behind a slot in the focusing cup, C, and a water-cooled target or anode, T, approximately 10 mm from the surface of C. The filament–focusing-cup assembly is at a negative voltage of between 30 and 50 kV, and the target is at ground potential. The electron beam strikes the target in a focal line, which acts as a line source of X-rays. There are usually two pairs of X-ray windows, W, through which the source is viewed at a small angle to the target surface, thus producing a foreshortened effective source, X, which is approximately square in one plane and a narrow line in the other. Focus dimensions on the target and maximum recommended power loading are shown for a number of standard inserts in Table 6.1.2.1. None of these are ideal for macromolecular crystallography. The assembly of a cathode, anode and windows – the tube insert – is inserted in a shock- and radiation-proof shield which is fixed to the table. Attached to the shield are X-ray shutters and filters, and sometimes brackets for bolting on X-ray cameras. A high-voltage connection is made to the tube by means of a flexible, shielded, shock-proof cable; nowadays, this high voltage is almost invariably full-wave rectified and smoothed DC.

6.1.2.2. Rotating-anode X-ray tubes

The sealed tubes described above are convenient and require little maintenance, but their power dissipation, and thus their X-ray output, is limited. For macromolecular crystallography, the most commonly used tubes are continuously pumped, demountable tubes with water-cooled rotating targets [see the

Table 6.1.2.1

reviews by Yoshimatsu & Kozaki (1977) and Phillips (1985)]. At present, these tubes mostly employ ferro-fluidic vacuum shaft seals (Bailey, 1978), which have an operational life of several thousand hours before they need replacement. The need for a beam with a small cross fire calls for a focal spot preferably not larger than 0.15 × 0.15 mm. This is usually achieved by focusing the electrons on the target to a line 0.15 mm wide and 1.5 mm long (in the direction parallel to the rotation axis of the target). The line is then viewed at an angle of 5.7° to give a 10:1 foreshortening. Foci down to this size can be produced on a target mounted close to an electron gun. For smaller focal spots, such as those of the microfocus tube described below, it is necessary to employ an electron lens (which may be magnetic or electrostatic) to produce on the target a demagnified image of the electron cross-over, which is close to the grid of the tube cathode.

The maximum power that can be dissipated in the target without damaging the surface has been discussed by Müller (1929, 1931), Oosterkamp (1948*a*,*b*,*c*), and Ishimura *et al.* (1957). The later calculations are in adequate agreement with Müller's results, from which the power W for a copper target is given by

$$W = 26.4\, f_1 (f_2 v)^{1/2}.$$

Here, W is in watts, f_1 and f_2 are the length and the width of the focal line in mm, and v is the linear speed of the target surface in mm s^{-1}; it is assumed that the surface temperature of the target reaches 600 °C, well below the melting point of copper (1083 °C). Thus, for a focal spot 1.5 × 0.15 mm and for an 89 mm-diameter target rotating at 6000 revolutions min^{-1} (v = 28 000 mm s^{-1}), Müller's formula gives a maximum permissible power loading of 2.5 kW or 57 mA at 45 kV. This agrees well with the experimentally determined loading limit.

Green & Cosslett (1968) have made extensive measurements of the efficiency of the production of characteristic radiation for a number of targets and for a range of electron accelerating voltages. Their results have been verified by many subsequent investigators. For a copper target, they found that the number of $K\alpha$ photons emitted per unit solid angle per incident electron is given by

$$N/4\pi = 6.4 \times 10^{-5} [E/E_k - 1]^{1.63},$$

where E is the tube voltage in kV and E_k = 8.9 keV is the K excitation voltage.

Accordingly, the number of $K\alpha$ photons generated per second per steradian per mA of tube current is 1.05 × 10^{12} at 25 kV and 4.84 × 10^{12} at 50 kV.

Of the generated photons, only a fraction, usually denoted by $f(\chi)$ (Green, 1963), emerges from the target as a result of X-ray absorption in the target. $f(\chi)$ decreases with increasing tube voltage and with decreasing take-off angle. It has a value of about 0.5 for E = 50 kV and for a take-off angle of 5°.

The X-ray beam is further attenuated by absorption in the tube window (~80% transmission), by the air path between the tube and the sample, and by any β-filters which may be used.

In a typical diffractometer or image-plate arrangement where no beam conditioning other than a β-filter is employed, the sample may be 300 mm from the tube focus and the limiting aperture at that point might have a diameter of 0.3 mm, so that the full-angle cross fire at the sample is 1.0 × 10^{-3} rad. The solid angle subtended by the limiting aperture at the source is 7.9 × 10^{-7} steradians. At 50 kV and 60 mA, the X-ray flux through the sample will be approximately 4.5 × 10^{7} photons s^{-1}. These figures are approximately confirmed by unpublished experimental measurements by Arndt & Mancia and by Faruqi & Leslie. It is interesting to note that the power in this photon flux is 5.8 × 10^{-8} W, which is a fraction of 2 × 10^{-11} of the power loading of the X-ray tube target.

Instead of simple aperture collimation, one of the types of focusing collimators described in Section 6.1.4.1 below may be used. They collect a somewhat larger solid angle of radiation from the target of a conventional X-ray source than does a simple collimator and some produce a higher intensity at the sample.

6.1.2.3. *Microfocus X-ray tubes*

Standard sealed X-ray tubes with a stationary target deliver a collimated intensity to the sample which is insufficient for most applications in macromolecular crystallography. These tubes have foreshortened foci between 0.4 and 2 mm^2 which do not lend themselves to efficient collimation by means of focusing mirrors or monochromators without introducing a cross fire in the beam that is too large for our purposes.

The situation is different with microfocus tubes, which are discussed in Section 6.1.4.2. Here, a relatively large solid angle of collection can make up for the lower power dissipation which results from the small electron focus.

6.1.2.4. *Synchrotron-radiation sources*

Charged particles with energy E and mass m moving in a circular orbit of radius R at a constant speed v radiate a power, P, into a solid angle of 4π, where

$$P = 88.47 E^4 I/R,$$

where E is in GeV, I is the circulating electron or positron current in ampères and R is in metres. Thus, for example, in a bending-magnet beam line at the ESRF, Grenoble, France, R = 20 m, and at 5 GeV and 200 mA, P = 554 kW.

For relativistic electrons, the electromagnetic radiation is compressed into a fan-shaped beam tangential to the orbit, with a

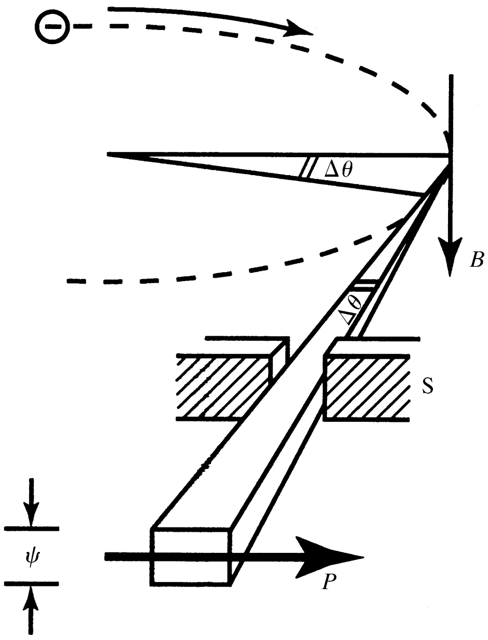

Figure 6.1.2.2
Synchrotron radiation emitted by a relativistic electron travelling in a curved trajectory. B is the magnetic field perpendicular to the plane of the electron orbit; ψ is the natural opening angle in the vertical plane; P is the direction of polarization. The slit, S, defines the length of the arc of angle, $\Delta\theta$, from which the radiation is taken. From Buras & Tazzari (1984).

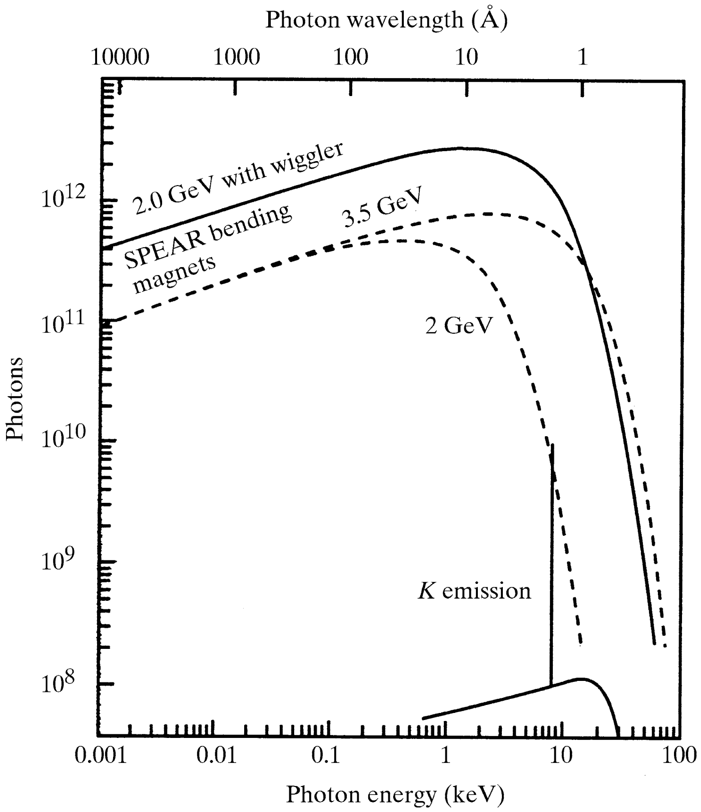

Figure 6.1.2.3
Comparison of the spectra from the storage ring SPEAR in photons s^{-1} mA^{-1} $mrad^{-1}$ per 1% band pass (1978 performance) and a rotating-anode X-ray generator, showing the Cu *K* emission line and the *Bremsstrahlung*. vertical opening angle $\Psi \simeq mc^2/E$, *i.e.* 0.1 mrad for $E = 5$ GeV (Fig. 6.1.2.2). This fan rotates with the circulating electrons; if the ring is filled with n bunches of electrons, a stationary observer will see n flashes of radiation every $2\pi R/c$ s, the duration of each flash being less than 1 ns.

The spectral distribution of synchrotron radiation extends from the infrared to the X-ray region; Schwinger (1949) gives the instantaneous power radiated by a monoenergetic electron in a circular motion per unit wavelength interval as a function of wavelength (Winick, 1980). An important parameter specifying the distribution is the critical wavelength, λ_c: half the total power radiated, but only ~9% of the total number of photons, is at $\lambda < \lambda_c$ (Fig. 6.1.2.6). λ_c (in Å) is given by

$$\lambda_c = 18.64/(BE^2),$$

where B (= $3.34E/R$) is the magnetic bending field in T, E is in GeV and R is in metres.

The orbit of the particle can be maintained only if the energy lost, in the form of electromagnetic radiation, is constantly replenished. In an electron synchrotron or in a storage ring, the circulating particles are electrons or positrons maintained in a closed orbit by a magnetic field; their energy is supplied or restored by means of an oscillating radiofrequency (RF) electric field at one or more places in the orbit. In a synchrotron designed for nuclear-physics experiments, the circulating particles are injected from a linear accelerator, accelerated up to full energy by the RF field, and then deflected onto a target with a cycle frequency of about 50 Hz. The synchrotron radiation is thus produced in the form of pulses of this frequency. A storage ring, on the other hand, is filled with electrons or positrons, and after acceleration the particle energy is maintained by the RF field; ideally, the current circulates for many hours and decays only as a result of collisions with remaining gas molecules. At present, only storage rings are used as sources of synchrotron radiation, and many of these are dedicated entirely to the production of radiation: they are not used at all, or are used only for limited periods, for nuclear-physics collision experiments.

Synchrotron radiation is highly polarized. In an ideal ring, where all electrons are parallel to one another in a central orbit, the radiation in the orbital plane is linearly polarized with the electric vector lying in this plane. Outside the plane, the radiation is elliptically polarized.

In practice, the electron path in a storage ring is not a circle. The 'ring' consists of an alternation of straight sections and bending magnets. Beam lines are installed at the bending magnets and at the insertion devices.

These insertion devices with a zero magnetic field integral, *i.e.* wigglers and undulators, may be inserted in the straight sections (Fig. 6.1.2.4). A wiggler consists of one or more dipole magnets with alternating magnetic field directions aligned transverse to the orbit. The critical wavelength can thus be shifted towards shorter values because the bending radius can be decreased over a short section, especially when superconducting magnets are used. Such a device is called a wavelength shifter. If it has N dipoles, the radiation from the different poles is added to give an N-fold increase in intensity. Wigglers can be horizontal or vertical. In a wiggler, the maximum divergence, 2α, of the electron beam is much larger than ψ, the vertical aperture of the radiation cone in the spectral region of interest (Fig. 6.1.2.2). If $2\alpha \ll \psi$, and if, in addition, the magnet poles of a multipole device have a short period, then the device becomes an undulator; interference takes place between the radiation of wavelength λ_0 emitted at two points λ_0 apart on the electron trajectory (Fig. 6.1.2.5). The spectrum at an angle θ to the axis observed through a pinhole consists of a single spectral line and its harmonics with wavelengths

$$\lambda_i = i^{-1}\lambda_0[(E/mc^2)^{-2} + \alpha^2/2 + \theta^2]/2$$

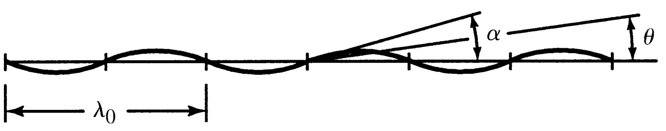

Figure 6.1.2.5
Electron trajectory within a multipole wiggler or undulator. λ_0 is the spatial period, α is the maximum deflection angle and θ is the observation angle. From Buras & Tazzari (1984).

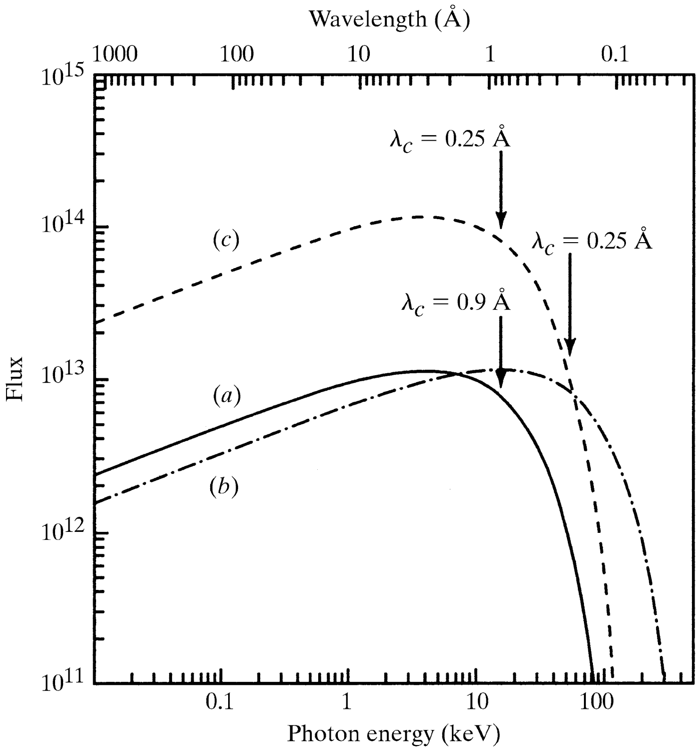

Figure 6.1.2.6

Spectral distribution and critical wavelengths for (*a*) a dipole magnet, (*b*) a wavelength shifter and (*c*) a multipole wiggler at the ESRF. From Buras & Tazzari (1984).

(Hofmann, 1978). Typically, the bandwidth of the lines, $\delta\lambda/\lambda$, is ~0.01 to 0.1, and the photon flux per unit bandwidth from the undulator is many orders of magnitude greater than that from a bending magnet. Undulators at the ESRF have a fundamental wavelength of less than 1 Å.

The spectra for a bending magnet and a wiggler are compared with that from a copper-target rotating-anode tube in Fig. 6.1.2.3.

6.1.3. Properties of the X-ray beam

We must now consider the properties of the X-ray beam necessary for the gathering of intensity data from single crystals of biological macromolecules. The properties of the beam with which we are concerned are:

(*a*) the size of the beam appropriate for the sample dimensions;
(*b*) the X-ray wavelength and its spectral purity;
(*c*) the intensity in photons s^{-1};
(*d*) the cross fire, that is, the maximum angle between rays in the beam;
(*e*) the temporal structure of the beam, that is, its stability or constancy, and for generators other than X-ray tubes, the duration and frequency of intensity pulses.

These properties cannot be considered in isolation since the requirements depend on the particular crystal under investigation (size, unit-cell dimensions, mosaic spread and resistance to radiation damage), on the geometry of the X-ray camera or diffractometer and on the detector used.

6.1.3.1. Beam size

The best signal-to-noise ratio in the diffraction pattern is secured when the sample crystal is just bathed in the X-ray beam, which is often taken to be about 0.2 to 0.3 mm in diameter. Unfortunately, many crystals are plate- or needle-shaped and present a greatly varying aspect to the beam. To date, no-one has described data-collection instruments in which the incident-beam dimension is changed automatically as the crystal is rotated; the next best thing is a versatile collimation system that makes use of interchangeable beam-limiting apertures.

6.1.3.2. X-ray wavelength

For X-ray tube sources, the main component of the beam is the characteristic radiation of the tube target. The vast majority of macromolecular structure determinations have been carried out with copper $K\alpha$ X-rays of wavelength 1.54 Å. These are reasonably well matched to the linear absorption coefficients of biological materials. Diffractometers and cameras are usually designed to permit data collection out to Bragg angles of about 30°, that is, to a minimum spacing of 1.54 Å, which is a convenient limit.

The next shortest, useful characteristic X-rays are, in practice, those from a molybdenum target (0.71 Å), but are rarely used in macromolecular crystallography.

The advantages of shorter wavelengths are a reduced absorption correction, smaller angles of incidence on the film, image plate or area detector, and, probably, a slightly smaller amount of radiation damage for a given intensity of the diffraction pattern. The disadvantage is a lower diffracted intensity, which is approximately proportional to the square of the wavelength. Crystal monochromators and specularly reflecting X-ray mirrors have a lower reflectivity for shorter wavelengths; most X-ray detectors, other than image plates and scintillation counters, are less efficient for harder X-rays (see Part 7).

At synchrotron beam lines where there is no shortage of X-ray intensity, it is now customary to select X-ray wavelengths of about 1 Å for routine data collection. Here, of course, it is possible to choose optimum wavelengths for anomalous-dispersion phasing experiments. This possibility is one of the major advantages of synchrotron radiation. The selection of a narrow wavelength band from the white radiation continuum (*Bremsstrahlung*) of an X-ray tube by means of crystal monochromators is not of practical importance: a tungsten-target X-ray tube operated at 80 kV produces about 1×10^{-5} 8 keV photons per steradian per electron incident on the target within a wavelength band, $\delta\lambda/\lambda$, of 10^{-3}; a copper-target X-ray tube at 40 kV produces about 5×10^{-4} $K\alpha$ photons per steradian per electron, that is, about 50 times more X-rays.

6.1.3.3. Spectral composition

Any X-rays outside the wavelength band used for generating the desired X-ray pattern contribute to the radiation damage of the sample and to the X-ray background. In the interests of resolving neighbouring diffraction spots in the pattern, one would require the wavelength spread, $\delta\lambda/\lambda$, in the incident radiation to be less than 5×10^{-3}. For the Cu $K\alpha$ doublet $(\lambda_{\alpha_2} - \lambda_{\alpha_1})/\lambda \simeq 2.5 \times 10^{-3}$ and the doublet nature of the line usually does not matter. On the other hand, the value of $(\lambda_\alpha - \lambda_\beta)/\lambda$ is 0.1, so the $K\beta$ component must be eliminated by means of a β-filter (a 0.15 mm-thick nickel foil for copper radiation) or by reflection from a crystal monochromator to avoid the appearance of separate $K\beta$ diffraction spots. The dispersion produced by a crystal monochromator is small enough to be ignored in most applications.

In synchrotron beam lines, the bandpass is usually determined by the divergence of the beam and is of the order of 10^{-4}. This is a smaller bandpass than is required for most purposes, and intensity can be gained by widening the bandpass by the use of an asymmetric-cut monochromator in spatial expansion geometry (Nave *et al.*, 1995; Kohra *et al.*, 1978). The intensity outside the monochromator bandpass is usually totally negligible.

6.1.3.4. *Intensity*

The intensity of the primary X-ray beam should be such as to allow data collection in a reasonably short time; increased speed is one of the main factors which has led to the popularity of synchrotron-radiation data collection as compared to data collection using conventional sources. Moreover, the radiation damage to the sample per unit incident dose is smaller at high intensities. This does not mean that ever more intense beams are necessary for today's protein-crystallography problems; very often, the speed of data collection is limited by the read-out time of the detector; the counting-rate capabilities of present-day X-ray detectors make it impossible to use in full the intensities available at some beam lines. With the widespread use of cryocrystallographic methods (Part 10), radiation damage is no longer as severe a problem as it once was.

No doubt, the day will come when available intensities will be so high that instantaneous structure determination will become a possibility, but this will require major advances in X-ray detectors, probably in the form of the development of large pixel detectors (*e.g.* Beuville *et al.*, 1997).

There is still some scope for increasing the intensity of X-ray beams from conventional sources, which offer the advantage of making measurements in the local laboratory instead of at some remote central facility.

6.1.3.5. *Cross fire*

The cross fire is defined as the angle or the half-angle between extreme rays in the beam incident on a given point of the sample. In the absence of focusing elements, such as specularly reflecting mirrors, the X-ray beam diverges from the source. A diverging beam can be turned into a converging one by reflection from a curved mirror or crystal. A crystal with constant lattice spacing can change the sign, but not the magnitude, of the angle between rays, whatever the curvature of the crystal; the deviation produced by a reflection anywhere on the surface of the crystal must always be twice the Bragg angle. It is possible to change a divergent beam into a convergent one with a different cross fire by specular reflection at a mirror or by means of a crystal in which the lattice spacing varies from point to point along the length of the plate. Such variable-spacing reflectors may be either artificial-crystal multilayers (Schuster & Göbel, 1997) or, less commonly, natural crystals whose spacing is modified by variable doping or by a temperature gradient along the crystal plate (Smither, 1982). In the neutron-scattering community, graded-spacing multilayer monochromators are usually referred to as 'supermirrors' (see Section 6.2.1.3.3 in Chapter 6.2).

The construction of curved mirrors and curved-crystal monochromators is discussed below.

As a general rule, the better the collimation of the incident X-ray beam, that is, the smaller the cross fire and the more nearly parallel the beam, the cleaner the diffraction pattern and the lower the background. Synchrotron-radiation sources permit a certain prodigality in X-ray intensity and the beams from them are thus usually better collimated than beams from conventional sources.

The useful degree of collimation depends on the crystal under investigation. The aim in the design of an instrument for data collection from single crystals must be to make the widths of the angular profiles of the reflection small, but these widths cannot be reduced beyond the rocking-curve width determined by the mosaic spread of the sample, however small the cross fire. The mosaic spread of a typical protein crystal is often quoted as being about 10^{-3} rad or about 3.4 minutes of arc. However, there are many crystals with much larger mosaicities; for such samples, the intensity of the X-ray beam, expressed as the total number of photons which strike the crystal, can be increased by permitting a larger cross fire.

The mosaic spread must be understood as the angle between individual domains of the mosaic crystal. These domains may be as large as 100 µm, that is, they may have dimensions not so very much smaller than those of the macroscopic crystal. The individual rocking-curve widths may be as small as 10 seconds of arc (50 µrad). Fourme *et al.* (1995) have discussed the implications of this degree of perfection if the collimation is improved to a stage where it can be exploited.

The way in which the cross fire influences the angular widths of the reflections depends on the instrument geometry. In a single-counter four-circle diffractometer, all reflections are brought onto the equator and the crystal is rotated about an axis perpendicular to the equatorial plane. The cross fire should, therefore, be small parallel to the equatorial plane, *i.e.* usually in the horizontal plane. The cross fire in the plane containing the rotation axis affects the angular width of the reflections much less, and it could thus be made larger in the interest of a high intensity.

The situation is different if the diffractometer is fitted with an electronic area detector, such as a CCD or other TV detector or a multi-wire proportional chamber (see Part 7). Here, the widths of reflections in upper levels are affected by the cross fire in the plane containing the crystal rotation axis, and the divergence or convergence of the beam in this plane should also be kept small.

With recording on photographic film or image plates, each exposure, or 'shot' or 'frame', corresponds to a crystal rotation that is usually many times larger than the angular width of a reflection. It is then less important to keep the cross fire small in the plane perpendicular to the rotation axis of the crystal.

In many collimation arrangements, the cross fire can be chosen independently in the two planes. In the absence of monochromators or mirrors, the cross fire is determined by beam apertures, which can be rectangular slits; it is, of course, simpler to employ circular holes, which give the same cross fire in both planes.

6.1.3.6. *Beam stability*

The synchrotron beam decays steadily after each filling of the ring as the number of stored positrons or electrons decays. Even with an X-ray tube operated from voltage- and current-stabilized supplies, the X-ray intensity changes with time as a result of contamination and roughening of the target surface. It is, thus, highly desirable to have a method of monitoring the beam incident on the sample, for example, by means of an ionization chamber built into the collimator (Arndt & Stubbings, 1988).

It should be noted that when the collimator contains focusing elements, the intensity at the sample can vary by several hundred per cent, depending on the exact alignment of the focusing mirrors or crystals and on the exact dimensions of the electron focus on the tube target.

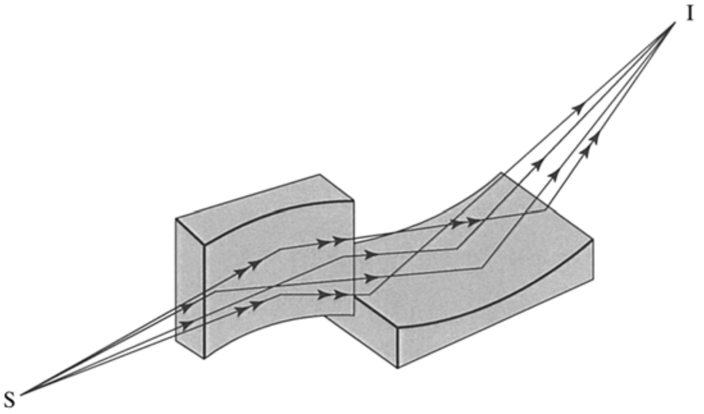

Figure 6.1.4.1
Production of a point focus by successive reflections at two orthogonal curved mirrors. Arrangement due to Kirkpatrick & Baez (1948) and to Franks (1955).

Intensity changes can be caused by mechanical movement of collimating components. Among these may be such unsuspected effects as flexing of the target surface with changes in cooling-water pressure.

The response of an incident-beam monitor may itself vary as a result of changes in temperature, barometric pressure, or humidity.

Synchrotron radiation from storage rings has a regular time-dependent modulation brought about by the rate of passage of bunches of electrons or positrons in the ring. For the great majority of measurements, this time structure has no effect, but at very high intensities, the counting losses are greater than they would be from a steady source.

6.1.4. Beam conditioning

The primary X-ray beam from the source is conditioned by a variety of devices, such as filters, mirrors and monochromators, to produce the appropriate properties for the beam incident on the sample.

6.1.4.1. X-ray mirrors

It is usually necessary to focus the X-ray beam in two orthogonal directions. This can be achieved either by means of one mirror with curvatures in two orthogonal planes or by two successive reflections from two mirrors which are curved in one plane and planar in the other; the two planes of curvature must be at right angles to one another. In the arrangement adopted by Kirkpatrick & Baez (1948) and by Franks (1955), the two mirrors lie one behind the other (Fig. 6.1.4.1) and thus produce a different degree of collimation in the two planes. Instead of this tandem arrangement, the mirrors can lie side-by-side, as proposed by Montel (1957), to form what the author calls a ‘catamegonic roof’ (Fig. 6.1.4.2). The mirrors are then best made from thicker material, and the reflecting surfaces are ground to the appropriate curvature. The same arrangement has been used by Osmic Inc. (1998) for their Confocal Max-Flux Optics, in which the curved surfaces are coated with graded-spacing multilayers.

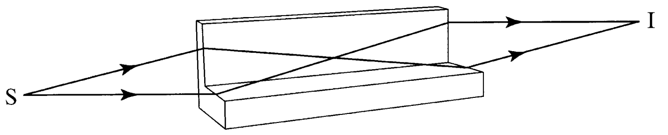

Figure 6.1.4.2
The ‘catamegonic’ arrangement of Montel (1957), in which two confocal mirrors with orthogonal curvatures lie side-by-side.

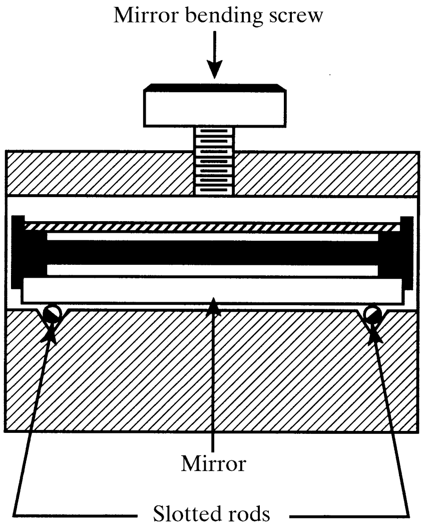

Figure 6.1.4.3
Mirror bender (after Franks, 1955). The force exerted by the screw produces two equal couples which bend the mirror into a circular arc. The slotted rods act as pivots and also as beam-defining slits.

Flat mirror plates can be bent elastically to a desired curvature by applying appropriate couples. Fig. 6.1.4.3 shows the bending method adopted by Franks (1955). A cylindrical curvature results from a symmetrical arrangement that produces equal couples at both ends. With appropriate unequal couples applied at the two ends of the plate, the curvature can be made parabolic or elliptical. Precision elliptical mirrors have been produced by Padmore *et al.* (1997); unequal couples are applied in this way. Cylindrically curved mirrors can be produced by applying a force at the tip of a triangular plate whose base is firmly anchored (Fig. 6.1.4.4). Lemonnier *et al.* (1978) first used this method for making curved-crystal monochromators. Milch (1983) described X-ray mirrors made in this way; the effect of the linear increase of the bending moment along the plate is compensated by the linear increase of the plate section so that the curvature is constant. An elliptical or a parabolic curvature results if either the width or the thickness of the plate is made to vary in an appropriate way along the length of the plate. Arndt, Long & Duncumb (1998) described a monolithic mirror-bending block in which the mirror plates are

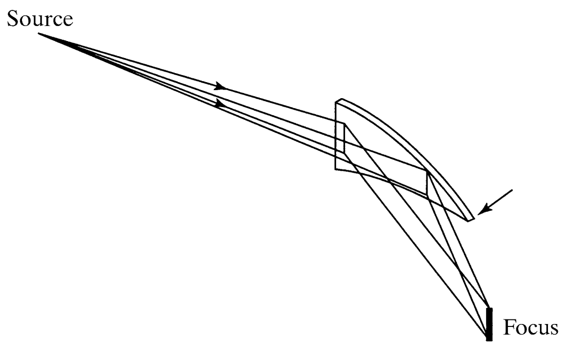

Figure 6.1.4.4
Triangular mirror bender as described by Lemonnier *et al.* (1978) for crystal plates and by Milch (1983) for glass mirrors. The base of the triangular plate is clamped and the bending force is applied at the apex along the arrow.

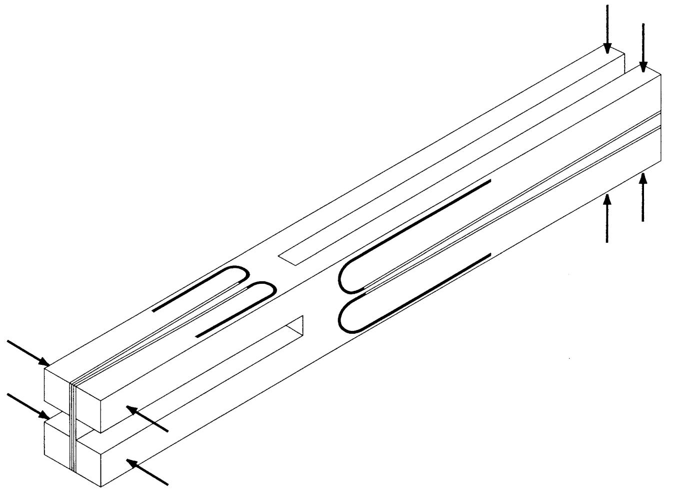

Figure 6.1.4.5
Mirror holder with machined slots for two orthogonal pairs of curved mirrors (after Arndt, Duncumb *et al.*, 1998).

inserted into slots cut to an elliptical curvature by ion-beam machining. The solid angle of collection is made four times larger than for a two-mirror arrangement by providing a pair of horizontal mirrors and a pair of vertical mirrors in tandem in one block (Fig. 6.1.4.5).

Mirror plates for these benders are usually made from highly polished glass, quartz, or silicon plates which are coated with nickel, gold, or iridium.

Mirrors for synchrotron beam lines that focus the radiation in the vertical plane are most often ground and polished to the correct shape, rather than bent elastically. Much longer mirrors can be made in this way.

The collecting efficiency of specularly reflecting mirrors depends on the reflectivity of the surface and on the solid angle of collection; this, in turn, is a function of the maximum glancing angle of incidence, which is the critical angle for total external reflection, θ_c. For X-rays of wavelength λ, measured in Å,

$$\theta_c \simeq 2.32\times10^{-3}(Z\rho/A)^{1/2}\lambda,$$

where Z is the atomic number, A is the atomic mass and ρ is the specific gravity of the reflecting surface.

Thus, for Cu $K\alpha$ radiation and a gold surface, $\theta_c \simeq 10$ mrad. The reflectivity of the mirror surface is strongly dependent on the surface roughness; for the reflectivity to be more than 50%, the r.m.s. roughness must not exceed 10 Å.

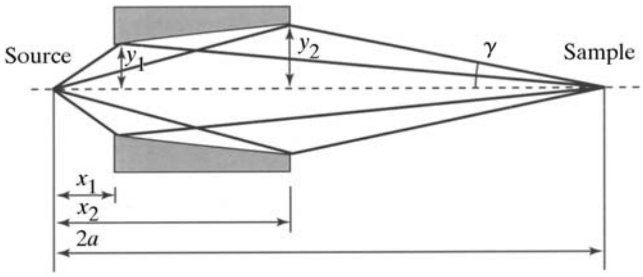

Figure 6.1.4.6
Ellipsoidal mirror for use with a microfocus X-ray tube, where x_1 is ~15 mm. The major axis, $2a$, may be up to 600 mm, whereas the exit aperture, $2y_2$, lies in the region 0.8–1.4 mm. The angle γ determines the cross fire on the sample and is less than 1 rad.

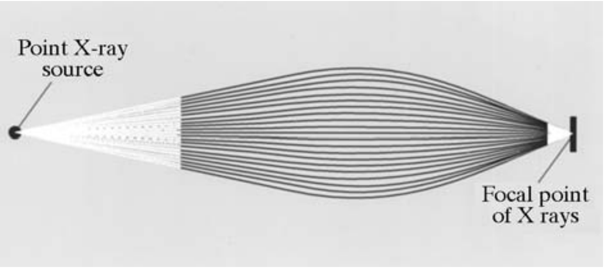

Figure 6.1.4.7
A polycapillary collimator (after Bly & Gibson, 1996).

It is not possible to design a reflecting collimator with a planar angle of collection greater than about $3\theta_c$. For the shorter wavelengths, in particular, variable-spacing multilayer mirrors (Schuster & Göbel, 1997) hold considerable promise. If the spacing at the upstream end of the mirror is 30 Å, the largest angles of incidence will be 26 and 17 mrad for 1.54 and 1.0 Å X-rays, respectively. By comparison, the critical angles at a gold surface for these radiations are 10 and 6.5 mrad, respectively.

6.1.4.2. Focusing collimators for microfocus sources

In most arrangements that include conventional X-ray tubes, the planar angle of collection is very small. A more efficient use is always made of the radiation from the target by a focusing collimator, which forms an image of the source on the sample (Fig. 6.1.4.6). The angle of collection should be as large as possible, while the cross fire, *i.e.* the angle of convergence, is kept small, say, at about 10^{-3} rad. It is possible to design focusing collimators based on gold-surfaced toroids of revolution (Elliott, 1965), which afford a planar angle of collection of about three times the critical angle for total external reflection, that is, about 30×10^{-3} rad.

Consequently, the mirror should *magnify* about 30 times, and if the image diameter, determined by a typical sample size, is to be 300 µm, the size of the focus should be about 10 µm. The solid angle of collection of such an imaging toroid is about 8×10^{-4} steradians, that is, more than 1000 times greater than the solid angle of a simple non-imaging collimator. The averaged mirror reflectivity achieved at present is about 0.3, so the microfocus tube and toroidal mirror combination produces a similar intensity at the sample as the conventional tube with a non-focusing collimator at about 300 times the power. Future increases of the reflectivity are likely as the surface roughness of the mirrors is improved.

A suitable microfocus tube has been described by Arndt, Long & Duncumb (1998); mirrors used with this tube were discussed by Arndt, Duncumb *et al.* (1998). The tube design allows the distance between the source and the mirror to be as little as 10 mm in order to achieve the necessary magnification without making the distance between the tube and the sample inconveniently long.

6.1.4.3. Other focusing collimators

There has been very active development in recent years of tapering capillaries for focusing X-rays, either as individual capillaries (see the review by Bilderback *et al.*, 1994), or in the form of multicapillary bundles. The latter were first described by Kumakhov & Komarov (1990); since then, they have undergone great improvements in the form of fused bundles (Bly & Gibson, 1996) (Fig. 6.1.4.7). Single capillaries have found the greatest use as X-ray concentrators, where a larger-diameter beam of X-rays enters the large end of a tapered capillary and is concentrated to a diameter of a few µm. Fused polycapillary bundles have been employed as focusing collimators for protein crystallography (MacDonald *et al.*, 1999). Both types of capillary optics are usually designed as multi-bounce devices, in which the X-rays undergo several, or many, reflections at the walls of the capillary; consequently the cross-fire half-angle at the output end has a value about equal to the critical angle for reflection at a glass surface or, perhaps, 4 mrad. This is sometimes too great for producing diffraction patterns with an optimum signal-to-background ratio.

Other methods of focusing X-rays, such as zone plates (Kirz, 1974) and refractive optics, are being investigated, but at present none of them can compare with toroidal reflectors for data collection from single crystals of macromolecules.

6.1.4.4. *Crystal monochromators*

When the X-rays from the tube target are specularly reflected by a mirror, the spectrum is cut off for X-rays below the shortest wavelength for which the critical angle is equal to the smallest angle of incidence on the mirror. For a typical mirror designed for Cu $K\alpha$ radiation, this cutoff wavelength might be about 0.75 Å, and the harder X-rays can be further attenuated by a β-filter. Of course, the more nearly monochromatic the radiation falling on the sample, the lower the radiation damage and the higher the spot-to-background ratio in the recorded patterns.

White radiation is almost completely eliminated by reflecting the primary X-ray beam using a natural or artificial (multilayer) crystal. The most commonly used type of plane monochromator for macromolecular crystallography is a single crystal of graphite. This material (HOPG, or highly ordered pyrolytic graphite) has a relatively large mosaic spread, typically about 0.4°, and it cannot separate the $K\alpha$ doublet. This separation is essential in most small-molecule investigations, but is unnecessary for macromolecular crystals, which rarely diffract beyond 1.5 Å, and disadvantageous where a high intensity of the beam reflected by the monochromator is the main consideration.

The intensity of the diffraction pattern obtained with a graphite monochromator is only about two or three times lower than that resulting from a β-filtered pinhole-collimated beam. The situation is different at synchrotron beam lines, which must incorporate a monochromator in order to select the desired X-ray energy band. Curved focusing crystals collect X-rays over a relatively large horizontal angular range and thus produce a beam with a horizontal convergence angle of up to several milliradians. Much more nearly parallel beams are produced by reflection at several crystals in tandem, often in the form of monolithic channel-cut monochromators. In present-day storage rings, the power density at the first optical element is of the order of 10 W mm^{-2} at wiggler and undulator beam lines. This amount of power can be dissipated by careful design of water-cooling channels (Quintana & Hart, 1995; van Silfhout, 1998). In addition, the monochromator crystal, usually of silicon or germanium, may be profiled to minimize distortions as a result of thermal stresses.

The next generation of insertion devices will subject the optical elements to loads of several hundred W mm^{-2}. Possible engineering solutions to the very severe heat-loading problem include the use of diamond crystals as reflecting elements. This material has a very high thermal conductivity, especially at low temperatures.

Chapter 6.2. Neutron sources

B. P. Schoenborn and R. Knott

6.2.1. Reactors

The generation of neutrons by steady-state nuclear reactors is a well established technique (Bacon, 1962; Kostorz, 1979; Pynn, 1984; Carpenter & Yelon, 1986; Windsor, 1986; West, 1989). Reactor sources that play a major role in neutron-beam applications have a maximum unperturbed thermal neutron flux, $\varphi_{\rm th}$, within the range $1 < \varphi_{\rm th} < 20 \times 10^{14}$ cm^{-2} s^{-1}. A research reactor is essentially a matrix of fuel, coolant, moderator and reflector in a well defined geometry (Fig. 6.2.1.1). The fuel is uranium, and neutron-induced fission in the isotope ^{235}U produces a number of prompt and delayed neutrons (slightly more than a total of two) and, on average, one of these is required to maintain the steady-state chain reaction (*i.e.* criticality). The heat generated (~200 MeV per fission event) must be removed, hence the need for an efficient coolant. In practice, the simultaneous requirements of complex thermal hydraulics and nuclear reaction kinetics must be addressed. The neutrons produced in the fission event have a mean energy of ~1 MeV, and a material is required to reduce this energy to ~25 MeV to take advantage of the larger fission cross section of ^{235}U in the 'thermal' energy range. Such a moderator is composed of a material rich in light nuclei, so that a large fraction of the neutron energy is transferred per collision.

There is an inherent maximum in neutron flux density imposed by the fission process (the number of excess neutrons produced per fission event), by the reduced density of neutron-generation material required for cooling purposes and by the heat-removal capacity of suitable coolants. Detailed design of reactor systems is essential to obtain the correct balance.

6.2.1.1. Basic reactor physics

Reactor physics is the theoretical and experimental study of the neutron distributions in the energy, spatial and time domains (Soodak, 1962; Jakeman, 1966; Akcasu *et al.*, 1971; Glasstone & Sesonske, 1994). The fundamental relation describing neutron kinetics is the Boltzmann transport equation (*e.g.* Spanier & Gelbard, 1969; Stamm'ler & Abbate, 1983; Weisman, 1983; Lewis & Miller, 1993). In theory, the transport equation describes the life of the neutron from its birth as a high-energy component of the fission process, through the various diffusion and moderation processes, until its ultimate end in (i) the chain reaction, (ii) leakage into beam tubes, or (iii) parasitic absorption (Williams, 1966). In practice, the complex nuclear reactions and the geometrical configurations of the component materials are such that a rigorous theoretical analysis is not always possible, and simplifying approximations are necessary. Nevertheless, well proven algorithms have been developed, and many have been included in computer codes (*e.g.* Hallsall, 1995).

On examination of the factors that influence the neutron flux distribution, there are three distinct but interdependent functions performed by the coolant, moderator and reflector. The coolant/moderator is of major importance in the fuelled region to sustain optimum conditions for the chain reaction, and the moderator/reflector is important in the regions surrounding the central core (Section 6.2.1.2). It should be noted that reactors for neutron-beam applications must be substantially undermoderated in order to provide a fast neutron flux at the edge of the core, which can be thermalized at the entry to the beam tubes. Most research reactors use H_2O or D_2O as the coolant/moderator.

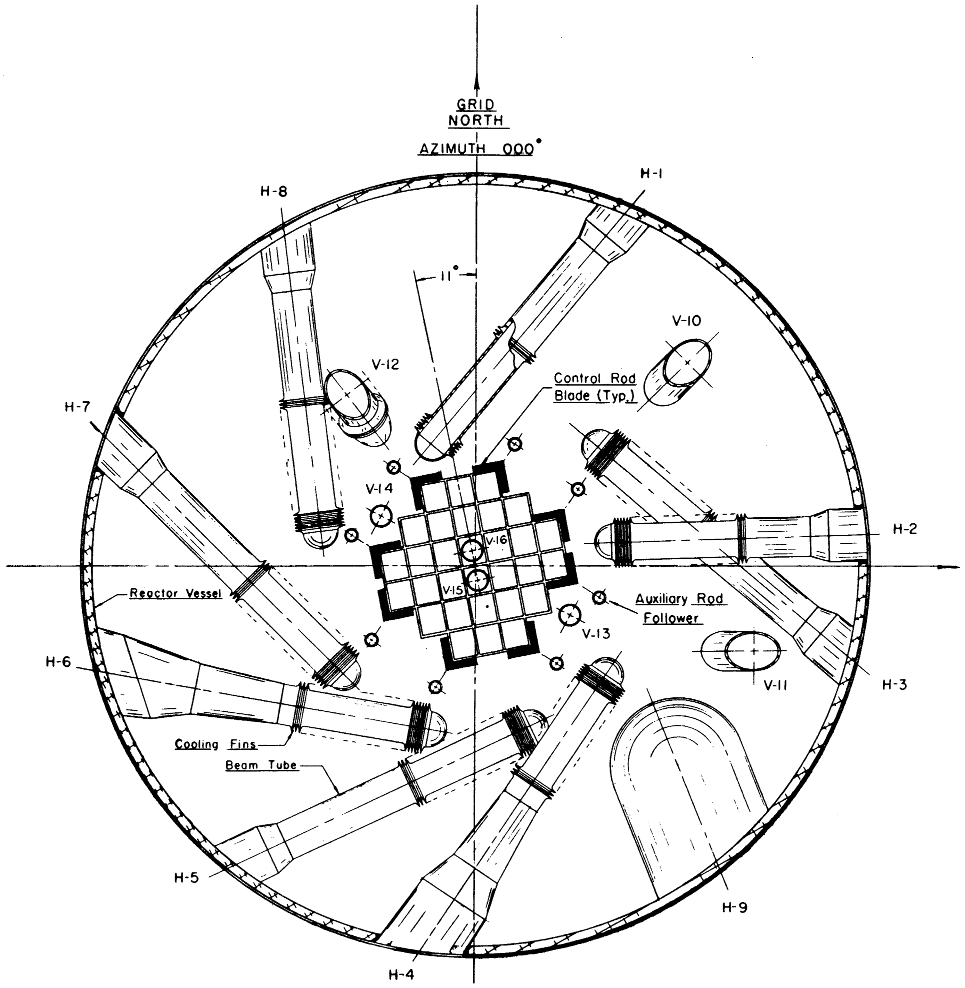

Figure 6.2.1.1
Schematic of the High Flux Beam Reactor at the Brookhaven National Laboratory (USA). The central core region (48 cm in diameter and 58 cm high) contains 28 fuel elements in an array surrounded by an extended D_2O moderator/reflector region. The diameter of the reactor vessel is approximately 2 m. All but one of the beam tubes are tangentially oriented with respect to the core. The cold neutron source is located in the H9 beam tube.

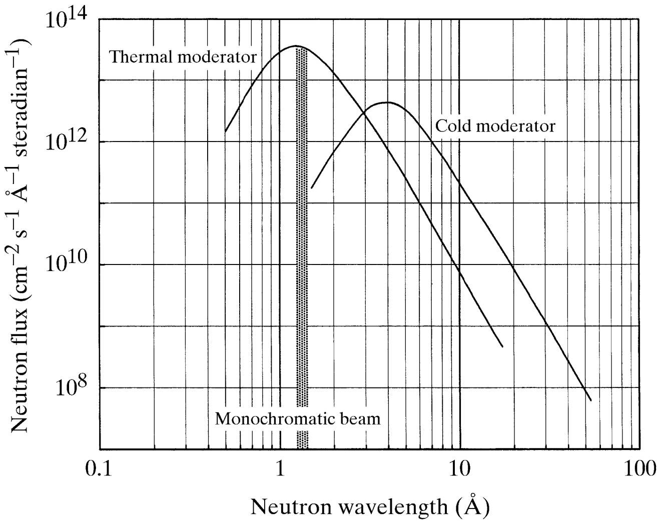

Figure 6.2.1.2

Neutron wavelength distributions for a thermal (310 K) and a cold (30 K) neutron moderator in a 'typical' dedicated beam reactor. The Maxwellian distribution merges with a $1/E$ slowing-down distribution at shorter wavelengths. A wavelength distribution for a monochromatic beam application on a thermal source is illustrated. It should be noted that, depending on the value of the mean wavelength for the monochromatic beam, harmonic contamination may be significant.

6.2.1.2. Moderators for neutron scattering

The moderator/reflector serves to modify the energy distribution of fast neutrons leaking from the central core, returning a significant number of thermalized neutrons to the core region to provide for criticality with a smaller inventory of fuel and providing excess neutrons for a range of applications, including neutron-beam applications. The moderator/reflector may be H_2O, D_2O, Be, graphite or a combination of these. Almost all choices have been used; however, the optimum is not achieved with any choice, and priorities must be set in terms of neutron-beam performance, other source activities and the reactor fuel cycle.

For neutron-beam applications, H_2O is the preferred reflector material since the moderation length is large and the absorption cross section low. Consequently, the thermal neutron flux peak is rather broad and occurs relatively distant from the core. While the exact position of the peak depends on the reactor core design, the peak width has a major impact on beam-tube orientation (Section 6.2.1.3). The combination of D_2O coolant/moderator–D_2O moderator/reflector provides a distinct advantage; however, for a number of technical reasons, the H_2O–D_2O combination is becoming more common, with the D_2O in a closed vessel surrounding the central H_2O-cooled core.

6.2.1.2.1. Thermal moderators

Neutrons thermalized within a 'semi-infinite' moderator/reflector typical of a steady-state reactor source establish an equilibrium Maxwellian energy distribution characterized by the temperature (T) of the moderator (Fig. 6.2.1.2). The wavelength, λ_m, at which the above distribution has a maximum is given by

$$\lambda_m = h/(5k_BTm_n)^{1/2}.$$

Depending on the width of the moderator and its composition, the Maxwellian distribution merges with the $1/E$ slowing-down distribution from the reactor core to give a total distribution at the beam-tube entry.

Clearly, the neutron wavelength distribution will depend on the local equilibrium conditions. Since steady-state reactors typically operate with moderator/reflector temperatures in the range 308–323 K, the corresponding λ_m is about 1.4 Å (Fig. 6.2.1.2). However, it is possible to alter the neutron distribution by re-thermalizing the neutrons in special moderator regions, which are either cooled significantly below or heated significantly above the average moderator temperature. One such device of prime importance is the cold moderator in the form of a cold source.

6.2.1.2.2. Cold moderators

The thermal neutron distribution shown in Fig. 6.2.1.2 is not ideal for all experiments, since the flux of 5 Å neutrons is almost two orders of magnitude less than the peak. The solution is to introduce a cold region in the moderator/reflector. This is typically a volume of liquid H_2 or D_2 at ~10–30 K, and a Maxwellian distribution around this temperature results in a λ_m of ~4 Å. The geometric design of a cold-source vessel has been shown to be very important, with substantial gains in neutron flux obtained by innovative design. A re-entrant geometry approximately 20 cm in diameter filled with liquid D_2 at 10 K provides optimum neutron thermalization with superior coupling to neutron guides (Section 6.2.1.3.5) (Ageron, 1989; Lillie & Alsmiller, 1990; Alsmiller & Lillie, 1992).

6.2.1.3. Beamline components

Until recently, instrument design has been largely based on experience; however, in many cases, it is now possible to formulate a comprehensive description of the instrument and explore the impact of various parameters on instrument performance using an extensive array of computational methods (Johnson & Stephanou, 1978; Sivia *et al.*, 1990; Hjelm, 1996). In practice, it is the instrument design that provides access to the fundamental scattering processes, as briefly outlined in the following.

If a neutron specified by a wavevector $\mathbf{k}_1$ is incident on a sample with a scattering function $S(\mathbf{Q}, \omega)$, all neutron scattering can be reduced to the simple form

$$\frac{d^2\sigma}{d\Omega\, dE} = AS(\mathbf{Q}, \omega),$$

where A is a constant containing experimental information, including instrumental resolution effects. The basic quantity to be measured is the partial differential cross section, which gives the fraction of neutrons of incident energy E scattered into an element of solid angle Ω with an energy between E' and $E' + dE'$. The momentum transfer, $\mathbf{Q}$, is given in Fig. 6.2.1.3(*a*). The primary aim of a neutron-scattering experiment is to measure $\mathbf{k}_2$ to a predetermined precision (Bacon, 1962; Sears, 1989) (Fig. 6.2.1.3*b*). A generic neutron-scattering instrument used to achieve this aim is illustrated in Fig. 6.2.1.4. The instrument resolution function will be determined by uncertainties in $\mathbf{k}_1$ and $\mathbf{k}_2$, which are a direct consequence of (i) measures to increase the neutron flux at the sample position (to maximize wavelength spread, beam divergence, monochromator mosaic, for example) and (ii) uncertainties in geometric parameters (flight-path lengths, detector volume *etc.*).

6.2.1.3.1. Collimators and filters

In general, neutron-beam applications are flux-limited, and a major advantage will be realized by adopting advanced techni-

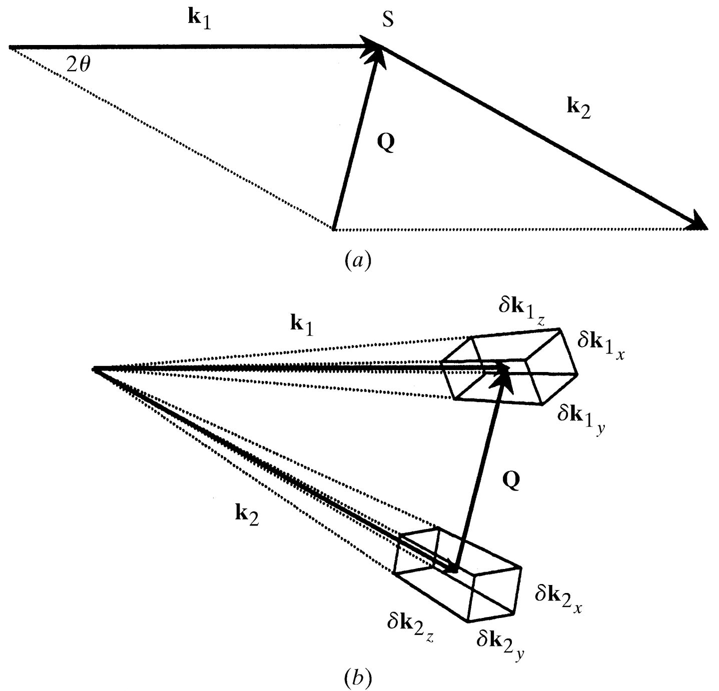

Figure 6.2.1.3

(*a*) Schematic vector diagram for an elastic neutron-scattering event. A neutron, $\mathbf{k}_1$, is incident on a sample, S, and a scattered neutron, $\mathbf{k}_2$, is observed at an angle 2θ leading to a momentum transfer, **Q**. (*b*) Schematic of an elastic neutron-scattering event illustrating the consequences of uncertainty in defining the incident neutron, $\mathbf{k}_1$, and determining the scattered neutron, $\mathbf{k}_2$. The volumes ($\delta\mathbf{k}_{1_x}$, $\delta\mathbf{k}_{1_y}$, $\delta\mathbf{k}_{1_z}$) and ($\delta\mathbf{k}_{2_x}$, $\delta\mathbf{k}_{2_y}$, $\delta\mathbf{k}_{2_z}$) constitute the instrument resolution function.

ques in flux utilization. A reactor neutron source is large, and stochastic processes dominate the generation, moderation and general transport mechanisms. Because of radiation shielding, background reduction and space requirements for scattering instruments, reactor beam tubes have a minimum length of 3–4 m and cannot exceed a diameter of about 30 cm. The useful flux at the beam-tube exit is thus between 10^{-5} and 10^{-6} times the isotropic flux at its entry.

The most important aspect of beam-tube design, other than the size, is the position and orientation of the tube with respect to the reactor core. The widespread utilization of D_2O reflectors enables significant gains to be obtained from tangential tubes with maximal thermal neutron flux, and minimal fast neutron and γ fluxes. A similar result is accomplished in a split-core design by orienting the beam tubes toward the unfuelled region of the reactor core (Prask *et al.*, 1993).

There are two major groups of neutron-scattering instruments: those located close to and those located some distance from the neutron source. The first group is located to minimize the impact of the inverse square law on the neutron flux, and the second group is located to reduce background and provide more instrument space. In both cases, the first beamline component is a collimator to extract a neutron beam of divergence α from the reactor environment. The collimator is usually a beam tube of suitable dimensions for fully illuminating the wavelength-selection device. The angular acceptance of a collimator is determined strictly by the line-of-sight geometry between the source and the monochromator. Some geometric focusing may be appropriate, and a Soller collimator may be used to reduce α without reducing the beam dimensions. For technical reasons, the primary collimator is essentially fixed in dimensions and secondary collimators of adjustable dimensions may be required in more accessible regions outside the reactor shielding.

Figure 6.2.1.4

A generic neutron-scattering instrument illustrating the classes of facilities and operators important to instrument design and assessment. Each class should be optimized and integrated into the overall instrument description.

Neutron-beam filters are required for two main reasons: (i) to reduce beam contamination by fast neutron and γ radiation and (ii) to reduce higher- or lower-order harmonics from a monochromatic beam. Numerous single-crystal, polycrystalline and multilayer materials with suitable characteristics for filter applications are available (*e.g.* Freund & Dolling, 1995).

6.2.1.3.2. *Crystal monochromators*

The equilibrium neutron-wavelength distribution (Fig. 6.2.1.2) is a broad continuous distribution, and in most experiments it is necessary to select a narrow band in order to define $\mathbf{k}_1$. Neutron-wavelength selection can be achieved by Bragg scattering using single crystals to give well defined wavelengths; by polycrystalline material to remove a range of wavelengths; by a mechanical velocity selector; or by time-of-flight methods. The method chosen will depend on experimental requirements for the wavelength, λ, and wavelength spread, $\Delta\lambda/\lambda$.

Neutrons incident on a perfect single crystal of given interplanar spacing d will be diffracted to give specific wavelengths at angle 2θ according to the Bragg relation. A neutron beam, α_1, incident on a single crystal of mosaicity β will provide

$$\Delta\lambda/\lambda = [(\cot\theta\cdot\theta)^2 + (\Delta d/d)^2]^{1/2},$$

where

$$(\Delta\theta)^2 = \frac{\alpha_1^2\alpha_2^2 + \beta^2(\alpha_1^2 + \alpha_2^2)}{\alpha_1^2 + \alpha_2^2 + 4\beta^2}$$

and α_2 is the divergence of the (unfocused) diffracted beam.

Crystals for neutron monochromators must not only have a suitable d, but also high reflectivity and adequate β. Under these conditions, neutron beams with a $\Delta\lambda/\lambda$ of a few per cent are obtained. Typical crystals are Ge, Si, Cu and pyrolytic graphite. In order to increase the neutron flux at the sample, a number of mechanisms have been developed. These include focusing monochromatic crystals, frequently using Si or Ge (Riste, 1970; Mikula *et al.*, 1990; Copley, 1991; Magerl & Wagner, 1994; Popovici & Yelon, 1995), as well as stacked composite wafer monochromators (Vogt *et al.*, 1994; Schefer *et al.*, 1996).

One limitation of the use of crystal monochromators is the absence of suitable materials with large d. Indeed, the longest useable λ diffracted from pyrolytic graphite or Si is ~5–6 Å.

6.2.1.3.3. *Multilayer monochromators and supermirrors*

Multilayers are especially useful for preparing a long-wavelength neutron beam from a cold source and for small-angle scattering experiments in which $\Delta\lambda/\lambda$ of about 0.1 is acceptable (Schneider & Schoenborn, 1984). Multilayer monochromators are essentially one-dimensional crystals composed of alternating layers of neutron-different materials (*e.g.* Ni and Ti) deposited on a substrate of low surface roughness. In order to produce multilayers of excellent performance, uniform layers are required with low interface roughness, low interdiffusion between layers and high scattering contrast. Various modifications (*e.g.* carbonation, partial hydrogenation) to the pure Ni and Ti bilayers improve the performance significantly by fine tuning the layer uniformity and contrast (Mâaza *et al.*, 1993). The minimum practical *d*-spacing is ~50 Å and a useful upper limit is ~150 Å. Multilayer monochromators have high neutron reflectivity (>0.95 is achievable), and their angular acceptance and bandwidth can be selected to produce a neutron beam of desired characteristics (Saxena & Schoenborn, 1977, 1988; Ebisawa *et al.*, 1979; Sears, 1983; Schoenborn, 1992*a*).

The supermirror, a development of the multilayer monochromator concept, consists of a precise number of layers with graded *d*-spacing. Such a device enables the simultaneous satisfaction of the Bragg condition for a range of λ and, hence, the transmission of a broader bandwidth (Saxena & Schoenborn, 1988; Hayter & Mook, 1989; Böni, 1997).

Polarizing multilayers and supermirrors (Schärpf & Anderson, 1994) facilitate valuable experimental opportunities, such as nuclear spin contrast variation (Stuhrmann & Nierhaus, 1996) and polarized neutron reflectometry (Majkrzak, 1991; Krueger *et al.*, 1996). Supermirrors consisting of Co and Ti bilayers display high contrast for neutrons with a magnetic moment parallel to the saturation magnetization and very low contrast for the remainder. With suitable modification of the substrate to absorb the antiparallel neutrons, a polarizing supermirror will produce a polarized neutron beam (polarization >90%) by reflection.

6.2.1.3.4. *Velocity selectors*

The relatively low speed of longer-wavelength neutrons (~600 m s^{-1} at 6 Å) enables wavelength selection by mechanical means (Lowde, 1960). In general, there are two classes of mechanical velocity selectors (Clark *et al.*, 1966). Rotating a group of short, parallel, curved collimators about an axis perpendicular to the beam direction will produce a pulsed neutron beam with λ and $\Delta\lambda/\lambda$ determined by the speed of rotation. This is a Fermi chopper. An alternate method is to translate short, parallel, curved collimators rapidly across the neutron beam, permitting only neutrons with the correct trajectory to be transmitted. This is achieved in the helical velocity selector, where the neutron wavelength is selected by the speed of rotation and $\Delta\lambda/\lambda$ can be modified by changing the angle between the neutron beam and the axis of rotation (Komura *et al.*, 1983). The neutron beam is essentially continuous, the resolution function is approximately triangular and the overall neutron transmission efficiency exceeds 75% in modern designs (Wagner *et al.*, 1992).

6.2.1.3.5. *Neutron guides*

In order for a collimator to be effective, its walls must absorb all incident neutrons. The angular acceptance is strictly determined by the line-of-sight geometry. Neutron guides can be used to improve this acceptance dramatically and to transport neutrons with a given angular distribution, almost without intensity loss, to regions distant from the source (Maier-Leibnitz & Springer, 1963). The basic principle of a guide is total internal reflection. This occurs for scattering angles less than the critical angle, θ_c, given by

$$\theta_c = 2(1-n)^{1/2},$$

where n is the (neutron) index of refraction related to the coherent scattering length, b, of the wall material, *viz*,

$$n = 1 - (\lambda^2 \rho b / 2\pi),$$

where ρ is the atom number density (in cm^{-3}). Among common materials, Ni with $b = 1.03 \times 10^{-12}$ cm, in combination with suitable physico-chemical properties, provides the best option, with a critical angle $\theta_c = 0.1\lambda$ (in Å). The dependence of θ_c on λ implies that guides are more effective for long-wavelength neutrons. With the introduction of supermirror guides with up to four times the θ_c of bulk Ni, both thermal and cold neutron beams are being transported and focused with high efficiency (Böni, 1997).

While a straight guide transports long wavelengths efficiently, it continues to transport all neutrons within the critical angle, including non-thermal neutrons emitted within the solid angle of the guide. This situation may be modified significantly by introducing a curvature to the guide. Since a curved neutron guide provides a form of spectral tailoring (cutoff or bandpass filters), simulation is a distinct advantage in exploring the impact of guide geometry on neutron-beam quality (van Well *et al.*, 1991; Copley & Mildner, 1992; Mildner & Hammouda, 1992).

6.2.1.4. *Detectors*

The detection of thermal neutrons is a nuclear event involving one of only a few nuclei with a sufficiently large absorption cross section (^{3}He, ^{10}B, ^{6}Li, Gd and ^{235}U). The secondary products (fragments, charged particles or photons) from the primary nuclear event are used to determine the location. Depending on the geometry of the instrument, either a spatially integrating or a position-sensitive detector is required (Convert & Forsyth, 1983; Crawford, 1992; Rausch *et al.*, 1992). The relatively weak neutron source is driving instrument design towards maximizing the number of neutrons collected per unit time, and, in many cases, this leads to the use of multiwire or position-sensitive detectors. The main performance characteristics for detector systems are position resolution, number of resolution elements, efficiency, parallax, maximum count rate, dynamic range, sensitivity to γ background and long-term stability.

6.2.1.4.1. *Multiwire proportional counters*

The principles of a multiwire proportional counter (MWPC) are well established (Sauli, 1977) and have wide application. For thermal neutron detection (Radeka *et al.*, 1996), the reaction of choice is

$$^3\mathrm{He} + \mathrm{n} \rightarrow {}^3\mathrm{H} + \mathrm{p} + 764\ \mathrm{keV}.$$

The 191 keV triton and the 573 keV proton are emitted in opposite directions and create a charge cloud whose dimensions are determined primarily by the pressure of a stopping gas. Depending on the work function of the gas mixture, approximately 3×10^4 electron–ion pairs are created. Low-noise gas amplification of this charge cloud occurs in an intense electric field created in the vicinity of the small diameter (20–30 μm) anode wires (Radeka, 1988). Typical gas gains of ~10–50 lead to a total charge on the anode of ~50–100 fC. The efficiency of the detector is determined by the pressure of ^{3}He, and the spatial resolution and count-rate capability are determined by the detector geometry and readout system. The event decoding is selected from the time difference (Borkowski & Kopp, 1975), charge division (Alberi *et al.*, 1975), centroid-finding filter (Radeka & Boie, 1980), or wire-by-wire techniques (Jacobé *et al.*, 1983; Knott *et al.*, 1997). Present MWPC technology offers opportunities and challenges to design a detector system that is totally integrated into the instrument design and optimizes data collection rate and accuracy (Schoenborn *et al.*, 1985, 1986; Schoenborn, 1992*b*).

A concept related to the MWPC is the micro-strip gas chamber (MSGC). With the MSGC, the general principles of gas detection and amplification apply; however, the anode is deposited on a suitable substrate (Oed, 1988, 1995; Velletaz *et al.*, 1997). The MSGC can potentially improve the performance of the MWPC in some applications, particularly with respect to spatial resolution and count-rate capability.

6.2.1.4.2. *Image plates*

The principles underlying the operation of an image plate (IP) are presented in detail in Chapter 7.2. Briefly, the important difference between an IP for X-ray and neutron detection is the presence of a converter (either Gd_2O_3 or ^6Li). The role of the converter is to capture an incoming neutron and create an event within the IP that mimics the detection of an X-ray photon. For example, neutron capture in Gd produces conversion electrons that exit the Gd_2O_3 grains, enter neighbouring photostimulated luminescence (PSL) material and create colour centres to form a latent image (Niimura *et al.*, 1994; Takahashi *et al.*, 1996). A neutron IP may have a virtually unlimited area and a shape limited only by the requirement to locate the detection event in a suitable coordinate system. With a neutron-detection efficiency of up to 80% at ~1–2 Å, a dynamic quantum efficiency of ~25–30% can be obtained. The dynamic range is intrinsically $1{:}10^5$. The spatial resolution is primarily limited by scattering processes of the readout laser beam, and measured line spread functions are typically 150–200 µm. The γ sensitivity is high and may restrict the application to instruments with low ambient γ background.

Neutron IPs are integrating devices well suited to data-acquisition techniques with long accumulation times, such as Laue diffraction (Niimura *et al.*, 1997) and small-angle scattering. On-line readout is a distinct advantage (Cipriani *et al.*, 1997).

6.2.1.5. *Instrument resolution functions*

For accurate data collection, the instrument smearing contribution to the data must be known with some certainty, particularly when data are collected over an extended range with multiple instrument settings. A balance must be struck between instrument smearing and neutron flux at the sample position; however, careful instrument design can produce: (i) a good signal-to-background ratio, thereby partially offsetting the flux limitation, and (ii) facilities and procedures for determining the instrument resolution function (Johnson, 1986).

As an example, instrumental resolution effects in the small-angle neutron scattering (SANS) technique have been investigated in some detail. A 'typical' SANS instrument is located on a cold neutron source with an extended (and often variable) collimation system. The sample is as large as possible and the detector is large with low spatial resolution. The instrument is best described by pin-hole geometry. Three major contributions to the smearing of an ideal curve are: (i) the finite λ, (ii) $\Delta\lambda/\lambda$ of the beam and (iii) the finite resolution of the detector. Indirect Fourier transform, Monte Carlo and analytical methods have been developed to analyse experimental data and predict the performance of a given combination of resolution-dependent elements (*e.g.* Wignall *et al.*, 1988; Pedersen *et al.*, 1990; Harris *et al.*, 1995).

6.2.2. Spallation neutron sources

Another phenomenon, quite different from the fission process (Section 6.2.1), that will produce neutrons uses high-energy particles to interact with elements of medium to high mass numbers. This process, called spallation, was first demonstrated by Seaborg and Perlman, who showed that the bombardment of nuclei by high-energy particles results in the emission of various nucleons. The nuclear processes involved in spallation (Prael, 1994) are complex and are summarized in Fig. 6.2.2.1. These processes have been investigated in some detail, and excellent background information is available (Hughes, 1988; Carpenter, 1977; Windsor, 1981). Present-day spallation sources typically use high-energy protons from an accelerator to bombard a heavy-metal target, such as W or U, and come in two types, using either a pulsed proton beam (*e.g.* ISIS or LANSCE) or a 'continuous' proton beam (SINQ).

The high-energy neutrons produced by spallation are moderated in a reflector region to intermediate energies and then reduced to thermal energies in a hydrogenous medium called the moderator (Russell *et al.*, 1996). These thermal neutrons are then extracted *via* beam pipes. A typical layout of a target system with reflectors and moderators is shown in Fig. 6.2.2.2.

The neutrons produced by the proton pulse travel along beam pipes as a function of their velocity, proportional to their energy.

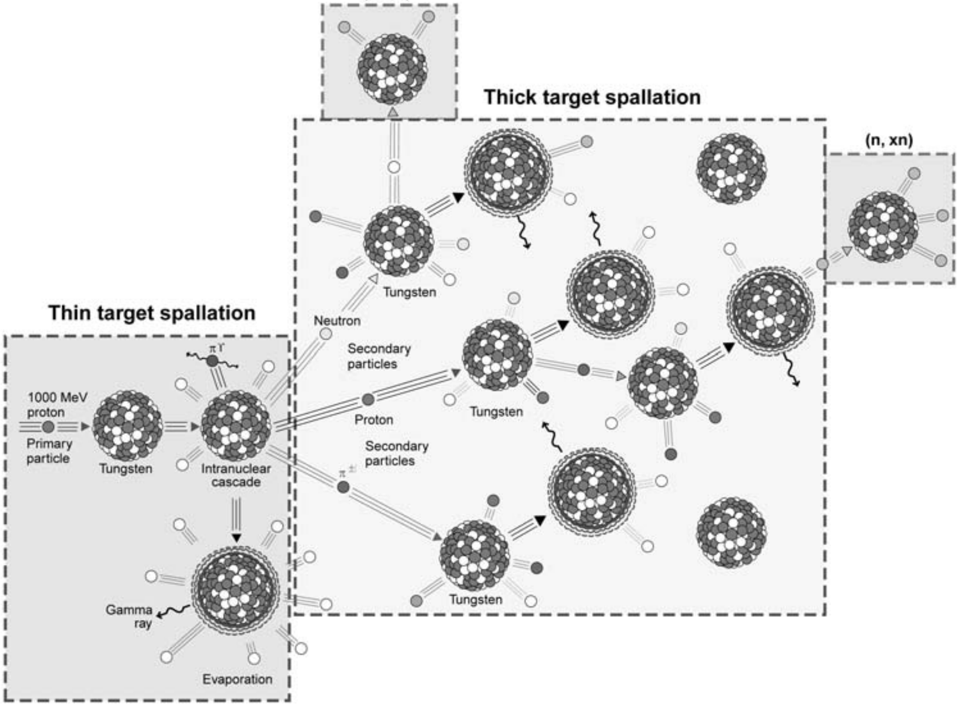

Figure 6.2.2.1
Schematic presentation of the various nuclear processes encountered in spallation. The numerical analysis of these processes is carried out by two Monte Carlo-based codes – the *LAHET* code models the higher-energy nuclear interactions, while the *HMCNP* code models the thermal interactions and the transport of neutrons to the sample.

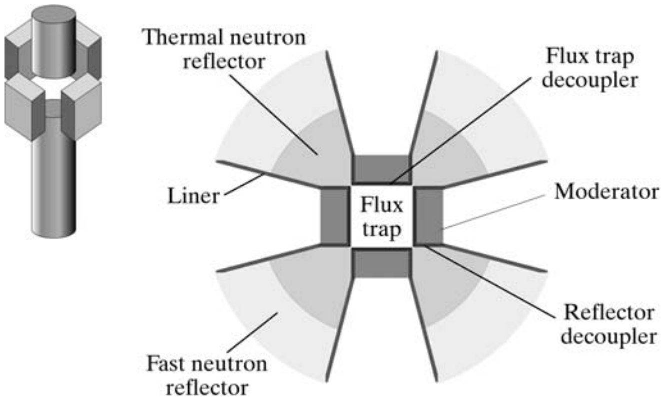

Figure 6.2.2.2
Schematic diagram of a spallation target module depicting the inner Be and outer Pb reflector. Moderators are positioned close to the flux trap, which is between the upper and lower tungsten targets. This schematic includes the location of the various decoupling agents (Cd) for fully decoupled moderators. For the partially coupled moderator system being fabricated for a protein-crystallography station at Los Alamos, the depicted decouplers affecting the given moderator are removed and replaced by a single decoupling layer placed between the outer Pb and the inner Be reflector. This can be done with a split-target arrangement that utilizes a two-tiered moderator system, permitting coupled moderators to be on one tier and decoupled moderators on the other.

At a given distance from the target, neutrons of different energies are observed to arrive as a function of time, with the short-wavelength neutrons arriving first, followed by the longer-wavelength neutrons. Diffraction experiments are therefore carried out with pulsed 'polychromatic' neutron beams as a function of time; a time-resolved Laue pattern results. Clearly, the energy resolution of these beams depends on the volume of the neutron source. To achieve high energy resolution, the volume from which thermal neutrons are extracted is limited to the moderator by suitable use of liners and poisons (Fig. 6.2.2.2) that prevent thermal neutrons produced in the reflector from streaming into the beam pipe (decoupled moderators). The use of liners and poisons achieves high energy resolution, but at the expense of flux. The omission or reconfiguration of liners and poisons allows higher flux, but results in lower energy (wavelength) resolution (see Section 6.2.2.2).

6.2.2.1. *Spallation neutron production*

Pulsed spallation neutrons are produced by protons generated by a particle accelerator (linac) with a frequency typically in the range 10 to 120 Hz. The proton pulses are often shaped in compressor rings to shorten the pulses from the millisecond range to less than a microsecond in duration, with currents reaching the sub-milliampere range at energies of 800 MeV or higher. The planned new spallation source at the Oak Ridge National Laboratory will have a proton energy of 1.2 GeV with a power of 1 MW and a repetition frequency of 60 Hz. The high-energy protons hit a cooled target (typically W or U) and produce high- and medium-energy neutrons in equivalent bursts. The fast neutrons are moderated in the surrounding reflector and returned to the moderator (Fig. 6.2.2.2). In addition to direct collision interactions, the high-energy neutrons also produce low-energy neutrons *via* (n, *x*n) reactions in the Pb and Be reflectors. Final moderation to the thermal energies used for diffraction experiments is completed *via* interactions with light elements, such as H_2O or liquid H_2, in the moderator module.

6.2.2.2. *Moderators*

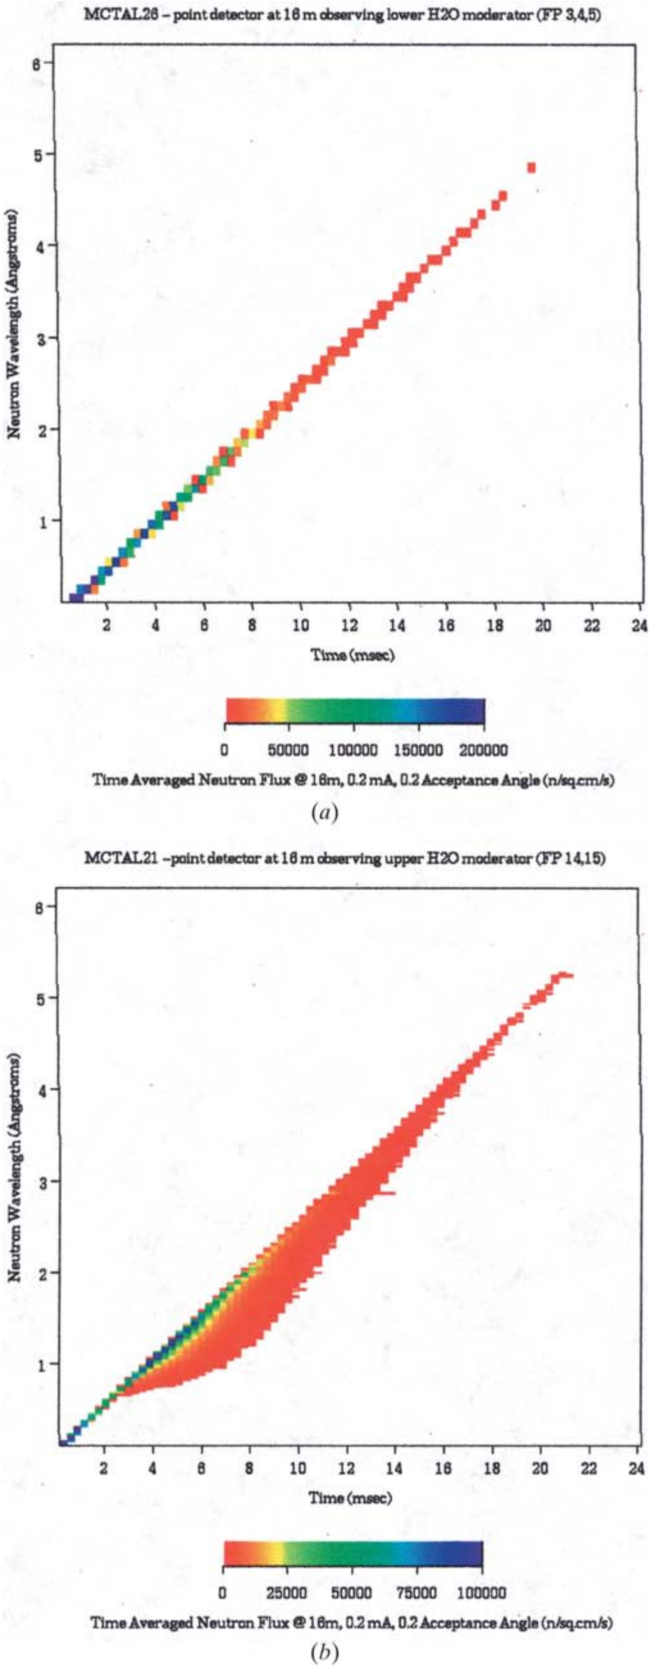
Moderators for pulsed spallation neutron sources are nearly always composed of hydrogenous material of about 1 l in volume. Either a thermal or fast reflector surrounds the moderator. Reflectors composed of materials with strong neutron slowing-down properties, such as Be or D_2O, are called thermal reflectors; fast reflectors are composed of materials with weaker slowing-down powers, such as Pb or Ni. In order to retain a narrow pulse width in time, thermal neutrons produced in the reflector region are prevented from reaching the moderator module by judicious use of liners and poisons (typically Cd or Gd) that allow transmission of fast (high and intermediate energy) neutrons, but are opaque to thermal neutrons. Such a moderator arrangement is said to be decoupled, and all thermal neutrons extracted by the beam pipe originate in the moderator itself. For a 0.25 µs-long proton pulse, the target (W or U) produces a fast neutron burst of about 0.5 µs in duration. These very high energy neutrons are slowed down in the reflector and are reflected back into the moderator to produce a thermal neutron pulse of about 1 µs duration. Since thermal neutrons produced in the reflector are prevented from reaching the moderator by the use of liners and poisons, the experiment sees only thermal neutrons originating in the moderator.

By moving the decoupling and poison layers away from the moderator and into the reflector, one can redefine how actively a reflector communicates *via* neutrons with a moderator and how some of the thermal neutrons produced in the reflector are extracted (Schoenborn *et al.*, 1999). The result is an increase in flux, both peak- and time-integrated, but at the expense of the sharply defined time distribution. With the elimination of all liners and poisons, a fully coupled system is obtained with a flux gain of about 6× but with poorer wavelength resolution. The wavelength distribution at a given distance from the moderator is shown in Fig. 6.2.2.3(*a*) for the fully decoupled case and in Fig. 6.2.2.3(*b*) for the fully coupled case. For a decoupled moderator, the slowing-down power of the reflector is not as critical as it is for the coupled one. In the coupled moderator, it is beneficial to use a thermal reflector in the volume immediately surrounding the moderator because this enhances the peak thermal neutron flux. The decay constant of the neutron pulse can be tailored to match the diffractometer resolution by using a composite reflector composed of an inner thermal reflector and an outer fast reflector. The outer reflector can have a moderate thermal neutron absorption cross section, or the inner reflector can be decoupled from the outer reflector in the same manner that a moderator is decoupled from a reflector. The decay constant can then be varied by simply adjusting the size of the inner reflector (Russell *et al.*, 1996). The wavelength or energy distribution of thermal neutrons produced in the moderator is dependent on the temperature of the moderating medium, as described in Section 6.2.1.2.

For neutron protein crystallography, a moderator with an intermediate temperature between a cold and thermal moderator would be most appropriate. This can be achieved with a composite moderator composed of a thermal and a cold moderator in a symbiotic configuration, or a cold methane system.

6.2.2.3. *Beamline optics*

A chosen wavelength band (say, 1 to 6 Å) is selected by the use of rotating disks (called choppers) composed of neutron absorbing and transparent material. These choppers are synchronized to the proton pulse. The T0 chopper can open the



(*a*)

(*b*)

Figure 6.2.2.3
Neutron flux given as a time–wavelength spectrum for (*a*) a fully decoupled system and (*b*) for a fully coupled system. Both spectra are based on Monte Carlo codes (*LAHET* and *HMCNP*) and are calculated for a target-to-sample distance of 10 m. Comparison of such Monte Carlo results calculated using the geometry of an existing beamline shows agreement with measured values to within 10%.

beam a short time after the impact of the proton pulse and stop the high- and intermediate-energy radiation from reaching the sample and the detector. The T1 chopper can select the long-wavelength edge and prevent frame overlap. Since the T0 chopper is designed to stop the initial γ and high-energy neutron radiation, it is usually made of thick (30 cm) blades of Ni, while the T1 chopper is simpler in construction since it is designed to stop only thermal neutrons.

The flight-path lengths of relevant spallation neutron instruments are quite long; the Los Alamos Spallation Neutron Source has a 28 m path length for its protein crystallography station on a partially decoupled moderator. For a fully decoupled system, a flight-path length of 10 m would provide adequate energy resolution.

For protein crystallography, a beam divergence matched to the mosaicity of the crystal provides the best peak-to-background ratio. For such cases, a beam divergence of $\pm 0.1^\circ$ can be achieved using circular collimating disks of Boral or Boron-Poly to form a cone that views most of the moderator (typically 12×12 cm) and channels the neutron beam onto the detector with a final aperture of millimetre dimensions. Another approach uses focusing mirrors, and calculations show that toroidal geometry will produce a gain in intensity of 1.5 to 2 times, depending on flight distance and beam divergence (Schoenborn, 1992*a*).

6.2.2.4. *Time-of-flight techniques*

Because of the time structure inherent at a spallation source, diffraction experiments are carried out as a function of time and use a large part of the neutron energy spectrum. For protein crystallography, this wavelength range might cover from 1 to 5 Å, depending on the unit-cell size and the moderator used. This is particularly advantageous and allows the collection of data in a quasi-Laue fashion (Schoenborn, 1992*a*) without the drawback of spot overlap normally encountered in Laue patterns. Data are collected in a stroboscopic fashion, synchronized to the pulsed nature of the source, with each separately recorded time frame producing a Laue pattern from a narrow, gradually increasing wavelength band. The summation of all time frames will produce a true Laue pattern. The collection and analysis of these quasi-Laue patterns (time frames) will eliminate spot overlap and yield a greatly improved peak-to-background ratio, since the integrated background is produced only by the small wavelength band responsible for a particular diffraction peak.

6.2.2.5. *Data-collection considerations*

Single-event-counting multiwire chambers with centroid-finding electronics (introduced in Section 6.2.1.4) are well suited for the type of time-sliced data collection that is mandatory for spallation neutron instruments. For large, high-resolution, multi-segmented detectors collecting about 100 time slices per cycle, data memories in the order of 100 million pixels are required. The number of time slices that needs to be collected to produce the optimum peak-to-background ratio depends on the characteristics (wavelength bandwidth) of the coupled or decoupled moderator.

Data-integration techniques are similar to those for the classic reactor case (Section 6.2.1.5), but contain a time (wavelength) dimension and no crystal stepping. The crystal is stationary and the reflection is 'scanned' as a function of time by the wavelength band. Time-dependent reflection overlap, caused by long pulse decay (particularly observed in fully coupled moderators), can be a problem. Such overlaps can be minimized by using a partially coupled moderator (Schoenborn *et al.*, 1999).

6.2.3. Summary

In the preceding sections, a brief overview has been presented of (i) the two main types of neutron sources and (ii) some of the primary components required to prepare a neutron beam for a neutron-scattering instrument. It has been assumed that as well as macromolecular crystallography, membrane and fibre diffraction, small-angle neutron scattering (see Chapter 19.4) is of interest. From a structural-biology user perspective, the advantages and disadvantages of reactor-based and spallation-source-based facilities are difficult to assess, since only very limited use of spallation sources has been documented. Direct comparisons between the performances of neutron-scattering instruments and sources are difficult, and would undoubtedly change as facilities are progressively upgraded (Carpenter & Yelon, 1986; Richter & Springer, 1998). Calculations show, however, that the use of time-of-flight techniques with partially coupled moderators on a spallation neutron source is ideal for structural-biology diffraction studies and promises to yield an effective gain of an order of magnitude in intensity (Schoenborn, 1996). When the protein crystallographic diffraction instrument now being built at LANSCE is completed in 2000, a more meaningful comparison will be possible between a premier spallation-source-based instrument and comparable reactor-based instruments.

In summary, the neutron source plays a pivotal role in the design and utility of an experiment in macromolecular crystallography, membrane and fibre diffraction, and small-angle neutron scattering. However, innovative design of the scattering instrument using the latest technology (*e.g.* image plates or large MWPCs) can partially offset certain negative impacts of the source and make an enormous difference to the instrument as a user facility. In general, neutron sources are national or regional facilities and consequently carry special requirements for user access. Therefore, a local, well equipped, medium-flux neutron source may be more suitable to test potential experiments and the premier international facility should be used only where required.

PART 7. X-RAY DETECTORS

Chapter 7.1. Comparison of X-ray detectors

S. M. Gruner, E. F. Eikenberry and M. W. Tate

7.1.1. Commonly used detectors: general considerations

This chapter summarizes detector characteristics and provides practical advice on the selection of crystallographic detectors. Important types of detectors for crystallographic applications are summarized in Section 7.1.2 and listed in Table 7.1.1.1. To be detected by any device, an X-ray must be absorbed within a detective medium through electrodynamic interactions with the atoms in the detecting layer. These interactions usually result in an energetic electron being liberated which, by secondary and tertiary interactions, produces the signal that will be measured, *e.g.* luminescence in phosphors, electron–hole pairs in semiconductors or ionized atoms in gaseous ionization detectors. As we shall see, there are many schemes for recording these signals. The various detector designs, as well as the fundamental detection processes, have particular advantages and weaknesses. In practice, detector suitability is constrained by the experimental situation (*e.g.* home laboratory X-ray generator *versus* synchrotron-radiation source; fine-slicing *versus* large-angle oscillations), by the sample (*e.g.* whether radiation damages it readily) and by availability. An assessment of detector suitability in a given situation requires an understanding of how detectors are evaluated and characterized. Some of the more important criteria are discussed below.

The *detective quantum efficiency* (DQE) is an overall measure of the efficiency and noise performance of a detector (Gruner *et al.*, 1978). The DQE is defined as

$$\mathrm{DQE} = (S_o/N_o)^2/(S_i/N_i)^2, \qquad (7.1.1.1)$$

where S is the signal, N is the noise, and the subscripts o and i refer to the output and input of the detector, respectively. The DQE measures the degradation owing to detection in the signal-to-noise ratio. For a signal source that obeys Poisson statistics, the inherent noise is equal to the square root of the number of incident photons, so that the incident signal-to-noise ratio is just $S_i/N_i = (S_i)^{1/2}$. The ideal detector introduces no additional noise in the detection process, thereby preserving the incident signal-to-noise ratio, *i.e.* $\mathrm{DQE} = 1$. Real detectors always have $\mathrm{DQE} < 1$ because some noise is always added in the detection process. The DQE automatically accounts for the fact that the input and output signals may be of a different nature (*e.g.* X-rays in, stored electrons out), since it is a ratio of dimensionless numbers.

A single number does not characterize the DQE of a system. Rather, the DQE is a function of the integrated dose, the X-ray spot size, the length of exposure, the rate of signal accumulation, the X-ray energy *etc.* Noise in the detector system will limit the DQE at low dose, while the inability to remove all systematic nonuniformities will limit the high-dose behaviour.

The *accuracy*, ρ, measures the output noise relative to the signal, *i.e.* $\rho = N_o/S_o$. For a Poisson X-ray source, it follows that the accuracy and the DQE are related by

$$\rho = (N_i \mathrm{DQE})^{-1/2}. \qquad (7.1.1.2)$$

This allows the determination of the number of X-rays needed to measure a signal to a given accuracy with a detector of a given DQE. The accuracy for an ideal detector is $1/(S_i)^{1/2}$, *e.g.* 100 X-rays are required to measure to 10% accuracy, and 10^4 X-rays are needed for a 1% accuracy. Nonideal detectors ($\mathrm{DQE} < 1$) always require more X-rays than the ideal to measure to a given accuracy.

Spatial resolution refers to the ability of a detector to measure adjacent signals independently. The spatial resolution is characterized by the *point spread function* (PSF), which, for most detectors, is simply the spread of intensity in the output image as a result of an incident point signal. An alternative measure of resolution is the *line spread function* (Fujita *et al.*, 1992).

Table 7.1.1.1
X-ray detectors for crystallography

(*a*) Commercially available detectors

Technology	Primary X-ray converter	Format
Film	AgBr	Area
Storage phosphor	BaFBr	Area
Scintillating crystal	NaI, CsI	Point
Gas discharge	Xe	Point, linear, area
Television	Phosphor	Area
CCD	Phosphor	Area
Silicon diode	Si	Linear, area
Avalanche diode	Si	Point, area

(*b*) Detectors under development

Technology	Primary X-ray converter	Format
Pixel array	Si, GaAs, CdZnTe	Area
Amorphous silicon flat panel + phosphor	CsI, Gd_2O_2S	Area
Amorphous silicon flat panel + photoconductor	PbI_2, CdZnTe, TlBr, HgI_2	Area

Although a detector might have a narrow PSF at 50% of the peak level, poor performance of the PSF at the 1% level and below can severely hamper the ability to measure closely spaced spots. It is important to realize that the PSF is a two-dimensional function, which is often illustrated by a graph of the PSF cross section; therefore, the integrated intensity at a radius R pixels from the centre of the PSF is the value of the PSF cross section times the number of pixels at that radius. Often the wings of the PSF decay slowly, so that considerable integrated signal is in the image far from the spot centre. In this case, a bright spot can easily overwhelm a nearby weak spot. Another consequence is that bright spots appear considerably larger than dim ones, thereby complicating analysis.

The *stopping power* is the fraction of the incident X-rays that are stopped in the active detector recording medium. In low-noise detectors, the DQE is proportional to the stopping power. A detector with low stopping power may be suitable for experiments in which there is a strong X-ray signal from a specimen that is not readily damaged by radiation. On the other hand, even a noiseless detector with a low stopping power will have a low DQE, because most of the incident X-rays are not recorded.

Unfortunately, many definitions of *dynamic range* are used for detectors. For an integrating detector, the dynamic range per pixel is taken to be the ratio of the saturation signal per pixel to the zero-dose noise per pixel for a single frame readout. For photon counters, the dynamic range per pixel refers to the largest signal-to-noise ratio, *i.e.* the number of true counts per pixel that are accumulated on average before a false count is registered. In practice, the dynamic range is frequently limited by the readout apparatus or the reproducibility of the detector medium. For example, the large dynamic range of storage phosphors is almost always limited by the capabilities of the reading apparatus, which constrains the saturation signal and limits the zero-dose noise by the inability to erase the phosphor completely. The number of bits in the output word does not indicate the dynamic range, since the number of stored bits can only constrain the dynamic range, but, obviously, cannot increase it.

The dynamic range is sometimes given with respect to an integrated signal that spans more than one pixel. For a signal S per pixel which spans M pixels, the integrated signal is MS, and, assuming the noise adds in quadrature, the noise is $N(M)^{1/2}$, yielding a factor of $(M)^{1/2}$ larger dynamic range. For most detectors, the noise in nearby pixels does not add in quadrature, so this is an upper limit.

The characteristics of a detector may be severely compromised by practical considerations of *nonlinearity*, *reproducibility* and *calibration*. For example, the optical density of X-ray film varies nonlinearly with the incident dose. Although it is possible to calibrate the optical density *versus* dose response, in practice it is difficult to reproduce exactly the film-developing conditions required to utilize the highly nonlinear portions of the response. A detector is no better than its practical calibration. This is especially true for area detectors in which the sensitivity varies across the face of the detector. The proper calibration of an area detector is replete with subtleties and constrained by the long-term stability of the calibration. Faulty calibrations are responsible for much of the difference between the possible and actual performance of detectors (Barna *et al.*, 1999).

The response of a detector may be nonlinear with respect to position, dose, intensity and X-ray energy. Nonuniformity of response across the active area is compensated by the *flat-field* correction. Frequently, nonuniformity of response varies with the angle of incidence of the X-ray beam to the detector surface, which is a significant consideration when flat detectors are used to collect wide-angle data. Although this may be compensated by an energy-dependent *obliquity* correction, few detector vendors provide this calibration. An X-ray image may also be spatially distorted; this *geometric distortion* can be calibrated if it is stable.

Other important detector considerations include the *format* of the detector (*e.g.* the number of pixels across the height and width of the detector). The format and the PSF together determine the number of Bragg orders that can be resolved across the active area of the detector. *Robustness* of the detector is also important: as examples, gas-filled area detectors may be sensitive to vibration of the high-voltage wires; detectors containing image intensifiers are sensitive to magnetic fields; or the detector may simply be easily damaged or lose its calibration during routine handling. Some detectors are readily damaged by too large an X-ray signal. *Count-rate* considerations severely limit the use of many photon counters, especially at synchrotron-radiation sources. Detector *speed*, both during exposure and during read out, can be important. Some detector designs are highly *flexible*, permitting special readout modes, such as a selected region of interest for use during alignment, or operation as a streak camera.

Ease of use is especially important. A detector may simply be hard to use because, for example, it is exceptionally delicate, requires frequent fills of liquid nitrogen, or is physically awkward in size. A final, often compelling, consideration is whether a detector is *well integrated into an application* with the appropriate analysis software and whether the control software is well interfaced to the other X-ray hardware.

7.1.2. Evaluating and comparing detectors

The DQE comprehensively characterizes the ultimate quantitative capabilities of an X-ray detector. The DQE may be determined from an analysis of the reproducibility of recorded X-ray test images of known statistics *via* equation (7.1.1.1): given M incident X-rays per exposure, the expected incident signal-to-noise is $(M)^{1/2}$. The DQE is determined by measuring the variance in the recorded signal in repeated measurements of the test image. Repetition of this process for different values of M maps out the DQE curve. Since the DQE is dependent on the structure of the image, the integration area, the X-ray background and the long-term detector calibration, it is essential that the test images realistically simulate these features as expected in experiments. Thus, if the detector is to be used to obtain images of diffraction spots, the test images should consist of comparably sized spots superimposed on a suitable background.

A comprehensive DQE determination is nontrivial and requires specialized tools, such as test masks, uniform X-ray sources *etc.* Unfortunately, published DQE curves are frequently incorrect and misleading. Users can, however, set up and perform a simple DQE assessment, detailed below, which gives a great deal of information about the sensitivity and usefulness of a given area detector. Other sources of stable X-ray spots (of appropriate size and intensity) can also be used in similar tests.

The materials needed are sheet lead and aluminium, a sewing needle, a stable collimated X-ray source, X-ray capillaries filled with saturated salt solutions, an X-ray shutter with timing capability and a scintillator/phototube X-ray counting arrangement. Arrange a fluorescent X-ray source to provide a diffuse X-ray signal. An X-ray capillary filled with a saturated solution of iron chloride makes a suitable source for a copper anode machine. Next, make an X-ray-opaque metal mask by punching a clean pinhole with a sewing needle in a lead sheet. The size of the hole should be representative of an X-ray spot, say 0.3 mm in diameter. The mask should be firmly and reproducibly secured a few cm from the fluorescent source at a wide angle to the incident beam. Using a scintillator/phototube combination, measure the number of X-rays per second emerging through the hole at a given X-ray source loading. A sufficient number of X-rays per measurement (say 10^5) is necessary to obtain accurate statistics (0.3%). This measurement should be repeated to verify the stability of the source.

This spot can now be recorded by the detector in question, using different integration times to vary the dose. 20 measurements at each integration time should give a reliable measure of the standard deviation in the signal. It is vital to move the position of the spot on the detector face for each exposure, taking care to move only the detector without disturbing the remainder of the experimental setup. Only by moving the detector is the fidelity of the calibrations tested. One subtlety is that the sensitivity of many detectors varies with the angle of incidence of the X-rays, so that it will be necessary to vary both the position and angle of the detector between exposures.

By using a wide range of integration times, both the sensitivity of the detector at low doses and the ultimately achievable measurement accuracy can be examined. These data may also highlight specific problems a detector might have, such as nonlinearity.

The DQE can be measured for a spot in the presence of a background if the lead pinhole mask is now replaced with a pinhole in a semitransparent aluminium foil. Choose the foil thickness to yield an appropriate background level, say 20% of the pinhole intensity. The uncertainty in the measurement of the spot intensity now results from the total counts in the integration area in addition to the uncertainty in determining the background. A wide PSF is especially harmful in this case, since many more pixels must be integrated to encompass the spot.

These evaluation procedures test only limited aspects of the detector, but in doing so, much is learned not only about the detector, but also about the degree to which the vendor is willing to work with the user, which is clearly of interest. The ultimate test for a crystallographer is whether a detector delivers good data in a well understood experimental protocol. Usually, values of $R_{\rm sym}$, the agreement of integrated intensities from symmetry-related reflections, are evaluated as a function of resolution. Low values of $R_{\rm sym}$ suggest good quality data. A much more stringent test can be made by comparing anomalous difference Patterson maps based on the Fe atom in myoglobin (Krause & Phillips, 1992). The limitation in these crystallography-based evaluations is that they tend to rely on robust, strongly diffracting crystals, which allow accumulation of good X-ray statistics even with insensitive detectors. Weakly diffracting and radiation-sensitive crystals are less forgiving.

7.1.3. Characteristics of different detector approaches

7.1.3.1. Point versus linear versus area detection

A point detector may be based on a scintillating crystal or a gas-filled counter, with the sensitive area defined by slits or a pinhole mask. The spatial resolution of such a detector can be made arbitrarily fine at the expense of data collection rate. Point detectors can have very high accuracy if the background is removed by energy discrimination. They find application in powder diffractometry and small-molecule crystallography, in which the reflections are widely dispersed, thereby simplifying measurement of individual reflections. Clearly, specimen and source stability are important for such work.

Throughput can be greatly increased by area detection, which is often required for macromolecular crystallography or investigations of unstable specimens. Typical area detectors, such as film, storage phosphors and charge-coupled devices (CCDs), are described below.

7.1.3.2. Counting and integrating detectors

Detectors can be broadly divided into photon counters and photon integrators. Photon counters have the advantage that some designs permit energy discrimination, allowing them to reject inelastically scattered radiation, thereby improving the signal-to-noise ratio. However, photon-counting detectors always have a count-rate limitation, above which they begin to miss events, or even become unresponsive (the time during which a detector misses events is known as dead time). Prototype systems have demonstrated linear count rates greater than 10^6 photon s^{-1}. Fabrication difficulties have limited the commercial availability of photon-counting detectors with large areas, high spatial resolution and high count rates. The count rate is a particular concern at modern synchrotron sources, which are capable of generating diffraction that delivers two or more photons to a pixel during one bunch time, an instantaneous count rate greater that 10^{10} photons per second per pixel. Integrating detectors are more typically used in situations where very high event rates are expected.

In contrast, integrating detectors have no inherent count-rate limitation, though at very high fluxes several sources of nonlinearity can theoretically become important, such as nonlinearity in the phosphor used to convert the X-ray image to a visible image. Integrating detectors, however, do not discriminate energy, and they have noise that increases with integration time. Nonetheless, film, image-plate and CCD integrating detectors are currently commercially available and in widespread use.

7.1.3.2.1. Photon-counting detectors

Commonly used photon counters include *scintillator/photomultiplier combinations*, *gas-filled counters* and *reverse-biased semi-conductor detectors*.

Scintillator/photomultipliers usually consist of a relatively thick crystal of a scintillator coupled to a high-gain photomultiplier tube. These detectors are generally designed to serve as point photon counters with moderate energy resolution. In order to perform this function, several constraints must be met:

(1) The scintillator crystal must be thick enough to have almost unity stopping power.

(2) It is necessary to collect as many of the converted visible photons as possible, so an optically clean scintillator crystal is used in a reflective housing to direct as many photons as possible toward the phototube.

(3) The scintillator must emit its light quickly, so as to minimize dead time, and be efficient, so as to emit much light. NaI:Tl, CsI:Na and CsI:Tl meet these constraints. NaI is more commonly used, but CsI may be preferred at higher X-ray energies because of its higher stopping power. Both materials are hygroscopic and are usually encased in hermetically sealed capsules with beryllium windows.

(4) The phototube is usually operated in its linear region for energy discrimination.

Scintillator/phototube combinations are relatively trouble-free and often have near-unity DQE. Their main limitations are count rates well below 10^6 photon s^{-1} and the lack of spatial resolution. Even so, such detectors are still preferred in many applications where the data are effectively zero- or one-dimensional.

Reverse-biased semiconductor detectors are designed to have a thick depletion zone in which charge can be efficiently collected and conveyed to an amplifier. X-rays that stop in the depletion zone produce electron–hole pairs; these are separated by the depletion zone field and the electrons are swept to the input of a low-noise amplifier. Single-photon counting can be readily achieved, even for low-energy X-rays, especially if the detector is cooled to minimize thermally generated charge. These detectors are typically fabricated as silicon diodes, but germanium and gallium arsenide are also used (Hall, 1995). Until recently, these devices were generally configured as point detectors or strip detectors consisting of a linear array of narrow sensitive regions, forming a one-dimensional detector (Ludewigt *et al.*, 1994). Two-dimensional arrays of square pixels are being developed, *e.g.* see the description of pixel array detectors below. In another device, the silicon drift detector, potentials are arranged in the silicon to funnel signals from a large area to a low-noise collection point (Rehak *et al.*, 1986). Such devices are being developed for both linear and area applications.

By increasing the electric field strength in an appropriately designed p-n junction in silicon, avalanche multiplication of the X-ray-induced electrons can be obtained as they move toward the anode where they are collected. This gives rise to a very high linear signal gain, with high speed and low noise. Arrays of such *avalanche photodiodes* as large as 8 × 8 elements, each 1 × 1 mm square, have been fabricated (Gramsch *et al.*, 1994; Farrell *et al.*, 1994).

Gas discharge (wire) counters make use of the ionization produced when an X-ray is stopped in the high-atomic-number gas, usually xenon, that fills the detector. A strong electric field between a fine anode wire and a cathode plane accelerates the products of the primary ionization to produce an ionizing multiplication (either a proportional or an avalanche discharge, depending on the field strength) that is detected as a charge pulse on one or both of the electrodes. The discharge is quenched by the presence of a few per cent of a second gas, *e.g.* methane or carbon dioxide. Gas discharge detectors have been configured in zero-, one- and two-dimensional versions and continue to be widely used in some applications. The venerable Geiger counter is in this class and is used for radiation monitoring and beam alignment in home laboratories. Properly designed gas discharge counters have very low noise, but the quantum efficiency depends critically on design, gas and X-ray energy.

Linear wire detectors have been used to record small-angle X-ray scattering. The localization of the X-ray event along the length of the detector is often performed by measuring the difference in arrival time of the charge pulses at the two ends of one of the electrodes (Barbosa *et al.*, 1989). The pulses are stretched to permit this measurement. One design uses a resistive anode wire to perform this function, whereas others configure the cathode plane as a delay line. Various two-dimensional arrangements of crossed planes of wires, broadly classified as multiwire proportional counters (MWPCs), have been widely used in crystallography, and some types have been commercially successful (Hamlin *et al.*, 1981; Blum *et al.*, 1987).

The design of MWPC area detectors has had difficulty keeping up with improvements in X-ray sources, particularly the high fluxes available at storage rings, and the shift toward use of higher-energy X-rays. The electric discharge at the heart of the technology has an inherent dead time associated with it. Added to this inherent dead time are the pulse propagation and processing times which limit the counting rate for a given wire. Thus, MWPCs are subject to a severe count-rate limitation. A second limitation of MWPCs has been their large pixel size and the relatively small number of pixels across the detector face, as well as parallax effects. These problems have been addressed by changes in the detector geometry (*e.g.* spherical drift chambers; Charpak, 1982), by microfabrication on glass substrates of the wires comprising the back plane of the detector, and by dividing the active area into small zones, each of which is read out independently. Robustness of MWPCs has also been a problem.

The dead time can be reduced by reducing the thickness of the detector. However, reducing the detector thickness reduces the X-ray stopping power. Increasing the gas pressure not only improves the quantum efficiency, but also helps to reduce the dead time further. Unfortunately, high gas pressure complicates the design of the front window of the detector. Despite these problems, two-dimensional gas-detector prototype modules with 200 μm square pixels have been constructed that are expected to have a local linear count-rate limit of 7 MHz mm^{-2} and a quantum efficiency above 80% at energies used in crystallography (see Sarvestani *et al.*, 1998).

7.1.3.2.2. Integrating detectors

X-ray film was the first area detector and has a long history of important contributions to the solution of structures and to X-ray imaging (Arndt *et al.*, 1977). In many applications, film has effectively been displaced because of its relative insensitivity caused by the high level of background fog, its multistep processing leading to long delays before digital data are obtained and its nonlinearity. However, X-ray film is still a superior integrator for long exposures, and lithographic film has much higher spatial resolution than any other area detector. Polaroid film in an X-ray cassette is an excellent diagnostic tool for beam alignment problems. And, in all cases, film is inexpensive.

Storage phosphors, also called image plates, are probably the most widely used area X-ray detector for crystallography at present, particularly in laboratories with conventional X-ray sources (Amemiya *et al.*, 1988; Eikenberry *et al.*, 1992). These sheets of material are a much improved functional replacement for X-ray film in many applications, including medical radiography and autoradiography in biological research. Storage phosphors are made from a BaFBr:Eu or other photostimulable phosphor coated on a suitable backing. These phosphors have the property that absorbed X-ray energy can be trapped in long-lived states within the phosphor grains, and that this energy can later be released as blue fluorescence upon photostimulation with red light. Grain-size distribution, grain orientation, binder choice and coating thickness are important parameters in the commercial preparation of the sheets.

The exposed phosphor sheet is raster-scanned with a finely focused red laser and the resulting photostimulated emission is recorded by a photomultiplier. The result is a digital image of the X-ray intensity distribution. The scanning can be done either on-line in self-contained systems or off-line in a separate scanning instrument. Scanning typically requires several minutes. In advanced scanners, this is reduced to several tens of seconds, where the limit is set by the time constant of the photostimulated emission process, which in turn determines the minimum time the laser should dwell on each pixel. The off-line scanner, preferred at synchrotron sources, permits a new exposure to be made while scanning is performed. Self-contained systems offer the advantages of simplified operation and the possibility of calibrating the detector, since only a single sheet of material is used in a mechanically stable setup.

Storage phosphors are typically read out with 100 µm square pixels, resulting in 2000 × 2500 pixel images for the common size of sheet. Larger formats are available. The wide PSF of storage phosphors makes the effective pixel size considerably larger than the nominal value. Some scanners permit smaller pixels, but this is of limited utility because there is a readout noise component associated with each pixel and too small a pixel harms the signal-to-noise ratio without improving data. The most critical component of the storage-phosphor system is the mirror assembly that gathers the photostimulated emission during readout. There are very few emitted photons for each stored X-ray (at the photon energies used for diffraction), and only a small fraction of these are detected in the photomultiplier (in some cases less than one per stored X-ray). This step in the detection process is critical in maintaining high quantum efficiency. Although image plates have an inherently wide dynamic range, the practical value is always limited by the scanner analogue-to-digital converter.

Television detectors. Numerous integrating detector designs based on television sensor technologies have been published and, in one case, produced commercially (Milch *et al.*, 1982; Arndt, 1991). These detectors span a wide range of design complexity and performance. The primary element is a phosphor screen, which converts the incident X-ray pattern to a light image that is directly or indirectly coupled to the sensor, such as a Vidicon or CCD. Many of the designs employ image intensifiers to raise the signal strength of the visible image above the noise of the sensor system. Some designs employ cameras operated at video rates, with frames accumulated in the attached computer or on videotape. Other designs use cooled cameras operated in a slow-scan mode, which greatly reduces noise. The X-ray exposure is integrated in the camera, then read out once at the end of the integration period.

Most of these systems would be classified as complex, but several of them are working reliably today in laboratories with conventional X-ray sources. The image intensifiers improve the DQE of the systems, while sacrificing dynamic range and image sharpness. In addition, intensifiers are sensitive to magnetic fields, requiring great care in their use if proper detector calibration is to be maintained.

Considerable enhancement to the television-type detector is made possible by the low-noise imaging capabilities of CCDs, described in Chapter 7.2. In this case, high DQE can be maintained without intensification when the CCD is cooled and read with slow-scan electronics. As such, these detectors are much more robust and have improved imaging qualities.

7.1.4. Future detectors

Commercially available X-ray detectors have evolved from X-ray film and point diffractometry to area gas-proportional counters, to image plates, and now to CCD detectors. Two new X-ray detector technologies are on the horizon. One is based on the large-area amorphous semiconductors and thin-film transistor arrays which are being intensively developed by many large companies for medical radiography (reviewed by Moy, 1999). The radiographic need is to be able to cover very large areas (*e.g.* 0.5 m^2) with a high-spatial-resolution detector that is sensitive to hard X-rays. A number of these detectors are at the moment (1999) poised for introduction, but they are specialized for radiographic applications and are poorly suited for relatively long, low-noise integration of low-energy X-rays. It remains to be seen whether the technology will succeed and whether it can be modified for quantitative crystallographic applications.

A second technology being developed specifically for quantitative X-ray diffraction is based on solid-state pixel array detectors (PADs) (Iles *et al.*, 1996; Datte *et al.*, 1999; Barna *et al.*, 1997; Rossi *et al.*, 1999). In a PAD, X-rays are stopped directly in a semiconductor and the resulting signal is processed by electronics integrated into each pixel. Direct conversion of X-rays into electrical signals in a high-grade semiconductor has many advantages: many signal electrons are produced for each X-ray, and the conversion medium is very linear, has low noise and is well understood. Since each pixel has its own electronics, there is enormous flexibility in performing local signal processing. In principle, PADs have tremendous advantages of sensitivity, flexibility, noise and stability. The challenge will be to make PADs of a size and format useful for crystallography, while still being sufficiently affordable to be commercially viable.

Chapter 7.2. CCD detectors

M. W. Tate, E. F. Eikenberry and S. M. Gruner

7.2.1. Overview

After more than 20 years of refinement, CCD (charge-coupled device) detectors have emerged as the most useable and accurate large-area detectors available for the X-ray energies of interest to crystallographers. CCDs are familiar as the imagers in television and digital cameras, but the scientific grade devices used in detectors are larger and have more pixels and a lower noise amplifier. CCD detectors are an assembly of several components: an energy converter (*e.g.* phosphor), an optical relay with or without gain (fibre optics, lenses and/or intensifier) and the imaging CCD.

Although many configurations have been used in the past, improvements in the size and quality of fibre-optic tapers have led to the possibility of direct coupling – eliminating intensifiers and lenses – so long as other components are carefully optimized at the same time (Eikenberry *et al.*, 1991). Optimizations include the phosphor, the CCD and electronics, and the elimination of unneeded optical interfaces. Current commercial designs employ just three elements: phosphor, taper and CCD (Fig. 7.2.1.1). This concept enabled the use of large tapers, machined square at the front, that can be stacked together to form mosaic arrays. Consequently, there is now no inherent limit to the size of a CCD detector.

7.2.2. CCD detector assembly

Any practical detector requires compromises in the choice of components to optimize those aspects most important to the diffraction problem at hand. The optimization of one detector characteristic often adversely affects other characteristics, so that it is often difficult to identify the 'best' component. Considerations are given below to aid in making judicious choices.

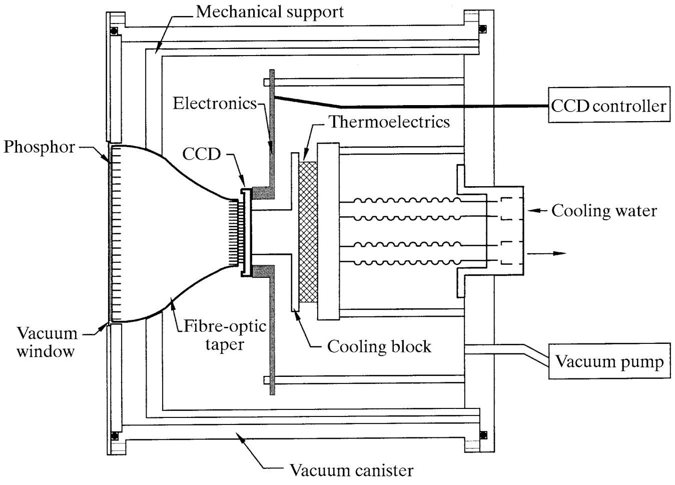

Figure 7.2.1.1
Schematic of a single-module CCD detector. The thin phosphor screen is behind a light- and vacuum-tight vacuum window and is coupled to a fibre-optic taper, which is, in turn, coupled to a CCD. The CCD is thermoelectrically cooled to 213 K and housed in a vacuum cryostat. Reproduced with permission from Tate *et al.* (1995).

Most fundamentally, a viable X-ray detector must have good quantum efficiency (see Section 7.1.1 in Chapter 7.1). Necessary, but not sufficient, are a high stopping power for X-rays and a large average signal per X-ray recorded in the CCD. The input signal passes through a sequence of stages and is transformed several times in the process. The statistics of this process are governed by the quantized nature of the signal, whether it be the initial X-ray photon, the visible photons produced in the phosphor, intermediate photoelectrons in intensifiers or the integrated charge in the CCD. To maintain a high detective quantum efficiency (DQE), the associated number of quanta per X-ray must be kept well above unity at each stage in the 'quantum chain'. There are several approaches that meet this criterion.

Crystallography applications generally benefit from large detective areas, whereas typical scientific CCDs are quite modest in size (*circa* 25 × 25 mm). The usual solution is to use fibre-optic tapers (which are more efficient demagnifiers than lenses; see Deckman & Gruner, 1986) to optically reduce a diffraction image excited in a larger phosphor screen. However, since optical image reduction is inherently inefficient, the reduction ratio is usually limited to about 4:1 before the number of visible photons per X-ray transmitted to the CCD becomes unacceptably low. Higher reduction ratios require image intensification *before* reduction (Moy, 1994; Naday *et al.*, 1995; Tate *et al.*, 1997) or there will be an unacceptable loss in DQE. Intensification *after* reduction can result in the same average recorded signal per X-ray. However, there is a significant probability that no quanta at all make it through the chain for many of the incident X-rays, thereby lowering the number of X-rays actually 'counted'.

Properties of the individual components affect other important detector characteristics as well. Below is a summary of important parameters for each of the components. Performance variations of CCD detectors from different vendors can most often be traced to the quality of the phosphor screen and the calibrations that are applied to the detector.

Phosphors. Although there are a bewildering variety of phosphor types, only a few are typically used with X-ray detectors (Shepherd *et al.*, 1995). A dense, high atomic number material is necessary to make the thin screens required for good spatial resolution while maintaining high X-ray stopping power. Gd_2O_2S:Eu offers high light output (>200 visible photons per 8 keV X-ray) and an emission spectrum matched to the typical CCD's spectral sensitivity peak in the red. Although there is a fairly prompt emission of most of the light (<1 ms to 10%), there is a long-term persistence which decays according to a power law: bright spots glow for seconds after an exposure has ended. This severely limits the dynamic range during fast framing, such as might be encountered in a synchrotron environment.

Other dopants for Gd_2O_2S, such as Tb and Pr, have much shorter persistence and are better suited to higher frame rates. These phosphors yield somewhat lower CCD signals because they emit fewer visible photons per X-ray and because their blue–green emission is less well matched to the CCD spectral sensitivity. Interestingly, Gd_2O_2S:Tb has one of the slowest 'prompt' emission (exponential decay) time constants, but is one of the fastest phosphors to decay to 10^{-4} (<10 ms), resulting in low persistence.

Thicker phosphors are needed at higher X-ray energies (>15 keV) to maintain high stopping power. This generally reduces spatial resolution. However, structured phosphors offer a way to increase thickness while limiting the lateral spread of the light. For example, CsI:Tl can be grown as an array of columnar crystals, resulting in a screen with enhanced resolution (Stevels & Schrama-de Pauw, 1974*a*, *b*; Moy, 1998). The spectral mismatch of this green-emitting phosphor is offset by the increased signal per X-ray expected at these higher X-ray energies. Recently, a (Zn,Cd)Se phosphor has been described that has excellent characteristics for X-ray energies above 12 keV; the stopping power at lower energies is compromised by absorption edges (Bruker AXS Inc.).

Fibre optics and lenses. Light transmission in image reduction is limited by n.a. × M^2, where n.a. is the numerical aperture of the optical system and M is the linear magnification factor ($M < 1$ corresponds to reduction). Lens systems have low values of n.a. when used in reduction, so there is only 2% light transmission for a 3:1 reduction with an f/1.0 lens. With a much higher n.a., fibre optics can typically transmit 13% with the same 3:1 reduction (Coleman, 1985). Such reducing tapers are produced by locally heating, then pulling, a fused bundle of optical fibres. Each fibre within the bundle becomes tapered in this process, thereby reducing the image scale from front to back of the bundle. The bundle structure introduces a characteristic 'chicken-wire' pattern into the image which must be removed *via* intensity calibration (Section 7.2.3). Tapers up to 165 mm in diameter are available.

To obtain good resolution, extramural absorbing fibres (EMAs) must be placed in the fibre optic to absorb light that propagates between fibres. These EMAs are often a more effective absorber in the blue part of the spectrum, with the result that a red-emitting phosphor yields somewhat poorer resolution. Another concern with fibre optics is radioactivity in the glass used to produce the optic, which manifests itself as random flashes ('zingers') in both the phosphor and the CCD (Section 7.2.3).

Although fibre-optic coupling is preferred in many situations, lenses are appropriate for use with image intensification, or in cases of image magnification, such as for microtomography, using high-resolution screens.

Image intensifiers allow large demagnification ratios without undue DQE loss (Moy, 1994). In these vacuum-tube devices, visible light produces photoelectrons in the photocathode of the intensifier, which in turn are accelerated under high potential onto a secondary phosphor screen. Each photoelectron excites many photons in the secondary phosphor, giving light amplification. Image resolution is retained either by magnetic, electrostatic or proximity focusing of the electrons. In the case of microchannel plate intensifiers, photoelectrons are restricted to cascade down hollow fibres. Intensifiers often have problems with stability and linearity, and they degrade resolution. Phosphor afterglow in the secondary phosphors is also a consideration. Intensifiers typically limit the input format to less than 80 mm in diameter, although one design uses a large (230 mm) radiographic intensifier (Moy, 1994; Hammersley *et al.*, 1997). The greatest drawbacks of image intensifiers are cost, availability, susceptibility to magnetic fields and lack of robustness.

CCDs. The low noise and high sensitivity of scientific CCDs have made CCDs the preferred imaging device in X-ray applications. Visible photons are converted to charge carriers in the silicon of the CCD, with a 30–40% quantum efficiency (q.e.) in the red, dropping to 5% in the blue owing to increased absorption by the controlling gate structure (the q.e. can be considerably higher for back-illuminated devices which, however, are expensive, fragile and difficult to obtain). The 'read noise' (noise with zero charge in the pixel) is routinely less than 10 electrons for scientific grade chips with pixel read rates of less than 1 MHz. When coupled to a good phosphor screen with a modest (*circa* 3:1) fibre-optic taper, signal levels in the CCD are typically 10–30 recorded electrons per 10 keV X-ray. This is above the CCD read-noise level, thereby allowing low-dose quantum-limited X-ray imaging.

A physically large CCD chip is usually desired to maximize the detector area, given the limited image reduction ratio. Devices from 2–4 cm on an edge with 1000 × 1000 to 2000 × 2000 pixels are available. These sizes match well to the largest of the fibre-optic tapers and are therefore most often used in detectors. Larger-format CCDs are available, but are harder to obtain and are expensive.

CCDs are usually cooled well below room temperature to minimize thermally generated dark current, an unwanted source of noise. The dark current drops by a factor of 2 for every 5–7 K drop in temperature. At 233 K, there is roughly one electron per pixel per second dark current for normal clocking operation. Since the dark current changes with temperature, the temperature must be well regulated (to within ±0.1 K to subtract the dark charge from an image reproducibly.

Most of the dark current comes from surface defects, not from the bulk silicon. Multiphase pinned (MPP) CCDs use charge implants within the pixel structure to move the charge collection region away from the surface, thereby reducing the dark current by several orders of magnitude. This is usually accompanied by a significant reduction in the maximum charge capacity ('full well') of a pixel. Even so, MPP CCDs are becoming the norm in most X-ray detectors.

Directly exposed CCDs. CCDs can directly image X-rays, although typical CCDs are not very efficient, since the charge collection region in the silicon is very thin (<10 μm). Thicker depletion regions can be fabricated in high-resistivity silicon wafers, improving X-ray collection efficiency to greater than 30% at 8 keV. Direct conversion of X-rays in silicon produces a large signal with excellent energy resolution. It is therefore possible to use the chip as an X-ray counting detector with the ability to discriminate in energy. To retain X-ray-energy measurement capability, however, there must be less than one X-ray per pixel per frame to avoid signal overlap. This requires a fast readout as well as large amounts of disk storage to handle the large number of files. The X-rays damage the CCD's electronic structure, resulting in a higher dark current within the exposed pixels. Care must be taken to shield non-imaging parts of the CCD, such as the output amplifier, which will adversely affect chip performance at even lower radiation dose.

7.2.3. Calibration and correction

Inhomogeneities within the detector components introduce nonuniformities in the output image of several per cent or more, both as geometric distortion and as nonuniformity of response. The response of the system varies not only with position, but also with the angle of incidence and X-ray energy. Optimal calibration of the detector should take into account the parameters of the X-ray experiment, seeking to mimic the experimental conditions as closely as possible: a uniform source of X-rays of the proper energy positioned in place of the diffracting crystal would be ideal. Realizing such a source is somewhat problematic, so the calibration procedure is often broken down into several independent steps. Calibration procedures are detailed in Barna *et al.* (1999) and are summarized below.

7.2.3.1. *Dark-current subtraction*

It is important to remove both the electronic offset and the accumulated dark charge from an X-ray image. Since the integrated dark current varies from pixel to pixel and with time, a set of images needs to be taken (with no X-rays), matched in integration time to the X-ray exposures. With a properly temperature-stabilized detector, the background images may be acquired in advance and used throughout an experiment. Because the background image has noise, it is common to average a number of separate backgrounds to minimize the noise.

7.2.3.2. *Removal of radioactive decay events*

Cosmic rays and radioactive decay of actinides in the fibre-optic glass produce large-amplitude isolated signals ('zingers') within an X-ray image. These accumulate randomly in position and in time. For the short exposures typical at synchrotron sources and for data sets with highly redundant information, the few diffraction spots affected by these events can be discarded with statistical analysis. For longer exposures, or for data with less redundancy, two (or more) nominally identical exposures can be taken and then compared pixel by pixel to remove spurious events (see Barna *et al.*, 1999).

7.2.3.3. *Geometric distortion*

Geometric distortions arise in the optical coupling of the system. If they are stable, the distortions can be mapped and corrected. Long-term stability is possible for a phosphor fibre-optically coupled directly to a CCD, since all distortions are mechanically fixed. Intensifier-based systems are subject to changes in magnetic and electric fields, hence stability is more of a problem.

Geometric distortions may be either continuous or discontinuous. Fibre optics often have shear between adjacent bundles of fibres. In this defect, one group of fibres will not run parallel to a neighbouring group, causing a discontinuity in the image. Rather than dealing with such discontinuities, tapers with low shear (less than one pixel maximum) are usually specified. Even with low shear, there is a continuous distortion (several per cent), which varies slowly over the face of the detector. Such distortion is inevitable, as the temperature profile cannot be precisely controlled in the large block of glass comprising the fibre optic as it is processed. To map this distortion, an image is taken of a regular array of spots. Such an image can be made by illuminating a shadow mask of equally spaced holes with a flood field of X-rays. Holes 75 μm in diameter spaced on a 1 × 1 mm square grid are adequate for mapping the distortions present in most fibre-optic tapers. Such masks have been lithographically fabricated in an X-ray opaque material, such as 50 μm tungsten foil (Barna *et al.*, 1999).

Given an image produced with this X-ray mask, the displacement map for every pixel in the original image can be computed as follows: find the centroid of each mask spot and its displacement relative to an ideal lattice. The array of spot positions and associated displacements can then be interpolated to find the displacement for each pixel in the original distorted image.

The displacement of a pixel from original to corrected image will not in general be a whole number. Rather, the intensity of a pixel will be distributed in a local neighbourhood of pixels in the corrected image centred about the position given in the displacement map. The size of the neighbourhood depends on the local dilation or contraction of the image; typically the intensity will be distributed in one to nine pixels. This distribution procedure yields a smooth intensity mapping. Applying corrections to mask images that have been arbitrarily displaced shows that the distortion correction algorithm is good to better than 0.25 pixels (Barna *et al.*, 1999).

The geometrical distortion is tied intimately to the correction of the response of the system (see below). Since distortions produce local regions of dilation or contraction of the image, pixels will, in general, correspond to varying sizes. This variation must be included in the flat-field calibration.

7.2.3.4. *Flat-field corrections*

Variation in response arises from nonuniformity in the phosphor, defects in the fibre optics and pixel-to-pixel variation in the sensitivity of the CCD itself. Of these, variations in the fibre optics are usually most pronounced, often with decreased transmission at the bundle interfaces, resulting in the characteristic 'chicken-wire' pattern. The response of the system is generally stable with time, although exposure to the direct beam at synchrotron sources will cause colour centres to form in the glass of the fibre optic. Recalibration of the system will correct for the reduced transmission in the exposed spot.

Light output from the phosphor depends on a number of factors: phosphor thickness, X-ray energy, angle of incidence and depth of conversion within the screen. X-ray photons are absorbed within phosphor grains with an exponentially decaying distribution as they travel deeper into the phosphor layer. Making the phosphor layer thicker increases the probability that the X-ray photons are absorbed, yielding an increase in the signal produced. But thicker phosphor layers also scatter the visible photons which one desires to collect in the CCD. At some point, the loss of light will be greater than the increase in X-ray stopping power and the net response will decrease. For one particular phosphor preparation, this appears to happen at *circa* 85% stopping power. The phosphor-screen resolution also falls with increasing screen thickness, although surprisingly slowly owing to the diffusive nature of the light scatter. These effects are discussed in Gruner *et al.* (1993).

Consider a given phosphor layer with thickness nonuniformity. For X-ray energies where the stopping power of the phosphor is low, regions of the phosphor with a thickness larger than the mean will be brighter owing to the increased X-ray stopping power. For energies at which X-rays are strongly absorbed, the increased opacity of the thicker regions of the phosphor will cause the response to go down. This illustrates the importance of calibrating the response of the system to the particular X-ray energy of interest.

In like manner, X-rays impinging on the phosphor at an angle away from the normal are presented with a longer path length and hence an increased stopping power. Also, because of the oblique angle, the distribution of visible-light production will be shifted toward the phosphor surface. Again, for strongly absorbed X-ray energies, the increase in the optical path for the light will cause the recorded signal to fall, whereas for X-rays not as strongly absorbed, the signal will increase.

To map the nonuniformity in response, one would ideally use a uniform source of X-rays of the proper energy placed at the position of the sample. This would calibrate the detector with the proper energy and angle of incidence for the diffraction data to be corrected. Correction factors are computed from a series of images taken of this uniform source. Sufficient numbers of X-rays per pixel must be collected to reduce the shot noise in the X-ray measurement to the required level (*e.g.* 40 000 X-rays per pixel must be acquired to correct to 0.5%).

Providing a truly uniform source with an arbitrary X-ray energy and angular distribution is difficult at best. Other sources can be used, however, with good results. Amorphous samples containing a variety of elements can be fabricated which produce X-ray fluorescence at various wavelengths when excited by a synchrotron beam (Moy *et al.*, 1996). These can be placed at the position of the sample, thereby mimicking the angular distribution of X-rays from the experiment. The fluorescence is not uniform in space, however, so that the actual distribution must be mapped by some means. Once mapped, however, these samples provide a stable calibration source.

Another alternative is to separate the calibration procedure into several parts, mapping the dependence at normal incidence and treating the angular dependence as a higher-order correction. By moving an X-ray source sufficiently far away, the detector can be illuminated at near-normal incidence with excellent uniformity. For example, an X-ray tube at 1 m distance can produce a field with uniformity better than 0.5% over a 10 × 10 cm area. A sum of images with sufficient X-ray statistics, taken with the area dilation of each pixel computed through the geometric distortion calibration, can be used to compute a pixel-by-pixel normalization factor. Again, this should be determined for the X-ray energy of interest. In practice, the appropriate energy may be approximated by a linear combination of several energies. However, the proper coefficients will need to be determined empirically. This can be judged in diffraction having broad diffuse features, because imperfections in the phosphor stand out clearly when the data are corrected using factors derived from the wrong X-ray energy.

7.2.3.5. *Obliquity correction*

It has been found empirically that the light output for a given X-ray energy has a quadratic variation with the angle of incidence. The quadratic coefficient varies with X-ray energy and may be either positive or negative. The angular dependence may be measured by illuminating the detector with a small stable spot of X-rays and recording the integrated dose at various angles of incidence. Given the placement of the detector in relation to the beam and sample, the angle of incidence at a particular pixel can be computed and can be used to find the correction factor needed. With this method, a change in the experimental setup does not require a new calibration, just the computation of a new set of coefficients. The combination of energy and obliquity sensitivity varies slowly and may be approximated by a quadratic or cubic fit to a surface as a function of X-ray energy and angle. The few coefficients defining this surface allow quick computation of the combined energy and obliquity factor with which to multiply the local flat-field correction for X-rays of known incident energy and angle.

The obliquity correction is often ignored, since the solution of structures from X-ray diffraction typically includes a temperature factor which also varies with angular position. Uncorrected angular dependence of detector response will be convoluted with the true temperature factor and often does not impede the solution of the structure.

These procedures do not allow correction to arbitrary accuracy, however. The calibration data are taken with uniform illumination, whereas diffraction spots are localized. Given a nonzero point spread in the detector, the computed correction factor arises from a weighted average of many illuminated pixels. The signal from a diffraction spot only illuminates a few pixels, so the true factor might well be different. This should be less of a problem as diffraction spots become larger, becoming more like a uniform illumination. Measurement for one detector showed 75 µm spots could be measured to 1% accuracy, whereas 300 µm spots could be measured to 0.3% accuracy (Tate *et al.*, 1995).

7.2.3.6. *Modular images*

The size of available fibre optics and CCDs and the inefficiencies of image reduction limit the practical imaging area of a single CCD system. Closely stacked fibre-optic taper CCD modules can be used to cover a larger area. Although the image recorded from each module could be treated as independent in the analysis of the X-ray data, merging the sub-images into one seamless image facilitates data processing. Each module will have its own distortion and intensity calibration. It is no longer possible to choose an arbitrary lattice onto which each distorted image will be mapped: the displacement and scaling must be consistent between the modules. This would be accomplished most easily by having a distortion mask large enough to calibrate all modules together, although it is possible to map the intermodule spacing with a series of mask displacements.

Flat-field correction proceeds as in the case of a single module detector after proper scaling of the gain of each unit is performed. There can potentially be a change in the relative scale factors between modules, since each is read though an independent amplifier chain. Multimodule systems emphasize the need for enhanced stability and ease of recalibration.

7.2.4. Detector system integration

Hardware interfacing. CCDs are operated, during both data acquisition and readout, by a dedicated hardware controller attached to a host computer, generally a PC. The requirements for the controller are complex and quite stringent in order to obtain low-noise operation. As with any high-speed electronics, noise increases with speed. Typically, pixel read rates of 100–500 kHz are used, although higher read rates can be used (and still preserve low-noise performance) for CCDs with multistage on-chip amplifiers. Some CCDs have multiple output amplifiers that increase pixel throughput by using parallel digitization channels. The entire CCD can also be read at reduced resolution by analogue summation of adjacent rows and/or columns on the chip (binning). This has the added benefit of increasing the signal-to-noise ratio for signals with low spatial frequency since there are fewer digitizations. Binning is highly recommended whenever the reduced resolution can be tolerated.

The time resolution of the detector can be further increased if the CCD array is used as frame storage. In this case, a portion of the imaging area is masked to X-rays, making it available for storage. The exposed area can be shifted rapidly into the masked area and a second exposure begun. Storage for five to ten subframes can easily be configured before readout is necessary. The time resolution is ultimately limited by the phosphor decay time and the time needed to shift the image. Although most

CCDs are capable of being operated in very flexible ways, flexible CCD controllers are expensive. The consequence is that few commercial CCD X-ray detectors permit use of all the available options.

The detector itself is contained in a cryostat with the low-noise parts of the controller nearby, either in a separate box connected by a short cable or mounted inside the cryostat itself. A longer cable carries the time-multiplexed digitized data to the computer. High-speed serial data technologies are under investigation to simplify this connection and will become imperative for the much larger format detectors that are being developed.

Several installations have constructed a safety shield in front of the detector that opens only when data are being collected. This device helps to protect the delicate front surface of the detector and is highly recommended.

Data acquisition software. There is a wide spectrum of computer configurations surrounding CCD detectors. The major tasks to be performed are operating the detector, controlling the beamline, storing raw data, correcting images and analysing diffraction patterns. In home laboratories, where exposure times are relatively long, a single PC typically handles these tasks. In another arrangement, the detector controller is really an embedded system, mostly unseen by the operator, making the detector a remote image server. The raw data or corrected images come to the user's workstation where subsequent analysis is performed. This circumvents the problem that the detector computer may be running a different operating system from the workstation. At storage-ring sources, where the data volume is very large, the detector is almost always configured as a remote image server; the user's workstation does not even need to be nearby. Clusters of remote computers that can perform tasks in parallel become attractive for streamlined data collection, correction and analysis from large data sets. Remote analysis over the internet is being explored by several storage-ring facilities.

Control software should be easy to use, but flexible and extensible. It should be easy to set up experiments and sequence the individual steps in an experiment: exposure, readout, correction, storage and crystal movement, and wavelength change for MAD experiments. Extensible software would permit a user-written macro to be run at each step in place of the detector primitive that is provided. For instance, if it were desired to collect two images at different exposure times for each position of the crystal, extensible software would make it easier to set up the experiment. Finally, the software should permit access to all of the readout modes of the detector. For instance, a detector may be capable of rapidly scanning a small region of interest for alignment purposes, or it may be capable of streak-mode operation for certain types of time-resolved experiments. Available CCD detector software for macromolecular applications has room for much improvement. Hopefully, software will continue to undergo rapid development. Standardization is especially needed.

7.2.5. Applications to macromolecular crystallography

Storage rings. CCD detectors have gained widespread acceptance for macromolecular crystallography at storage-ring sources, in part because of the high-quality data they give, but more for their speed, convenience and efficiency. Accurate data to high resolution are especially important for MAD phasing, and CCD detectors excel in this application. In the past with film, or even storage phosphors, teams of perhaps ten people were required to perform a synchrotron experiment; today, a single person per shift can perform an experiment. With increasing beam flux, improved X-ray optics and faster CCDs, it is often possible to collect full data sets in little more than an hour. Anticipated improvements in speed for CCD detectors should soon make it feasible to collect fine-sliced rotation data routinely; these data are expected to yield better structure solutions.

Home laboratories. Acceptance of CCD detectors for macromolecular crystallography at home laboratories has been slower, in part because there is not such a premium on speed, and in part because of cost. Diffracted spot sizes are larger than at synchrotrons, so highly accurate data should be obtainable. Fully automatic storage phosphor systems work quite well with conventional sources and at this time are lower in cost than large CCD detectors. However, they have a minimum cycle time, caused by the mechanics of the readout scheme, and the required exposure for a strongly diffracting crystal can best this time by a wide margin. Thus, for strongly diffracting specimens, CCD detectors can be significantly more efficient.

7.2.6. Future of CCD detectors

The basic principles of CCD detector technology are now well developed, but various incremental improvements have already been demonstrated and may be expected in commercial detectors. These include larger detector areas, faster read times (owing to both faster electronics and multiamplifier CCDs), more flexible control electronics, better optimized phosphors and calibrations, and, especially, better software. Lower-cost CCD detectors would certainly be welcome. It is easily predicted that the application of CCD detectors will continue to increase rapidly for at least several more years until displaced by even better technologies, such as pixel array detectors (see Section 7.1.4 in Chapter 7.1).

PART 8. SYNCHROTRON CRYSTALLOGRAPHY

Chapter 8.1. Synchrotron-radiation instrumentation, methods and scientific utilization

J. R. Helliwell

8.1.1. Introduction

Synchrotron radiation (SR) has had a profound impact on the field of protein crystallography. The properties of high spectral brightness and tunability have enabled higher-resolution structure determinations, multiple-wavelength anomalous-dispersion (MAD) techniques, studies of much larger molecular weight structures, the use of small crystals and dynamical time-resolved structural studies. The use of SR required development of suitable X-ray beamline optics for focusing and monochromatization of the beam, which had to be stable in position and spectral character, for rotating-crystal data collection. Finely focused polychromatic beams have been used for ultra-fast data collection with the most advanced SR sources, where a single bunch pulse of X-rays can be strong enough to yield Laue diffraction data. The optimal recording of the diffraction patterns has necessitated the development of improved area detectors, along with associated data-acquisition hardware and data-processing algorithms. Sample cooling and freezing have reduced and greatly diminished, although not eliminated, radiation damage, respectively. In turn, even smaller crystals have been used. However, new X-radiation damage challenges are being reached. The low emittance of SR sources, with their small source size and beam divergence, corresponds well with the small size and low mosaicity of protein crystal samples. The evolution of SR source spectral brightness each year over the last twenty years has changed by many orders of magnitude, a remarkable trend in technical capability.

8.1.2. The physics of SR

The physics of the SR source spectral emission was predicted by Iwanenko & Pomeranchuk (1944) and Blewett (1946), and was fully described by Schwinger (1949). It is 'universal' to all machines of this type, *i.e.*, wherever charged particles such as electrons (or positrons) travel in a curved orbit under the influence of a magnetic field, and are therefore subject to centripetal acceleration. At a speed very near the speed of light, the relativistic particle emission is concentrated into a tight, forward radiation cone angle. There is a continuum of Doppler-shifted frequencies from the orbital frequency up to a cutoff. The radiation is also essentially plane-polarized in the orbit plane. However, in high-energy physics machines, the beam used in target or colliding-beam experiments would be somewhat unstable; thus, while pioneering experiments ensued through the 1970s, a considerable appetite was stimulated for machines dedicated to SR with stable source position, for fine focusing onto small samples such as crystals and single fibres, and with a long beam lifetime for more challenging data collection. Crystallography has been both an instigator and major beneficiary of these developments through the 1970s and 1980s onwards. An example of a machine lattice (the ESRF) is shown in Fig. 8.1.2.1.

The properties of synchrotron radiation can be described in terms of the well defined quantities of high flux (a large number of photons), high angular brightness (also well collimated), high spectral brightness (also a small source size and well collimated), tunable, polarized, defined time structure (fine time resolution) and exactly calculable spectra. The precise definition of the spectral brightness is

$$\text{Spectral brightness} = \text{photons per s per mm}^2 \text{ per mrad}^2 \text{ per } (0.1\% \text{ bandwidth}). \qquad (8.1.2.1)$$

Care needs to be exercised to check precisely the definition in use (Mills *et al.*, 2005). The mrad^2 term refers to the radiation solid angle delivered from the source, and the mm^2 term to the source cross-sectional area. Mills *et al.* (2005) concluded that the units given in equation (8.1.2.1), which do not follow the SI code for

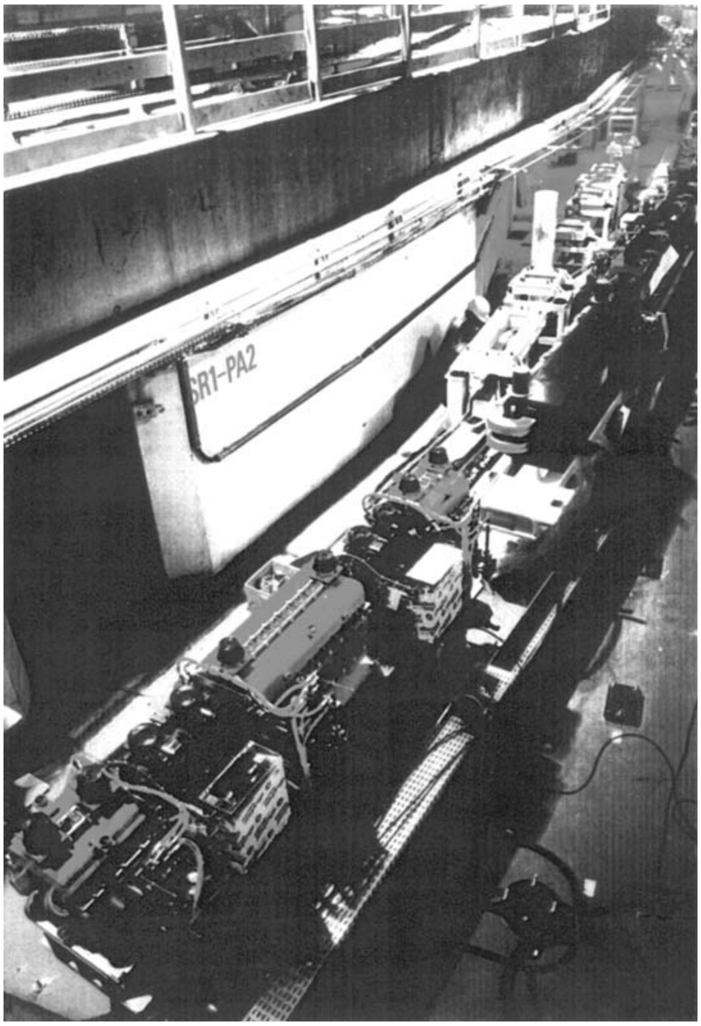

Figure 8.1.2.1
The ring tunnel and part of the machine lattice at the ESRF, Grenoble, France.

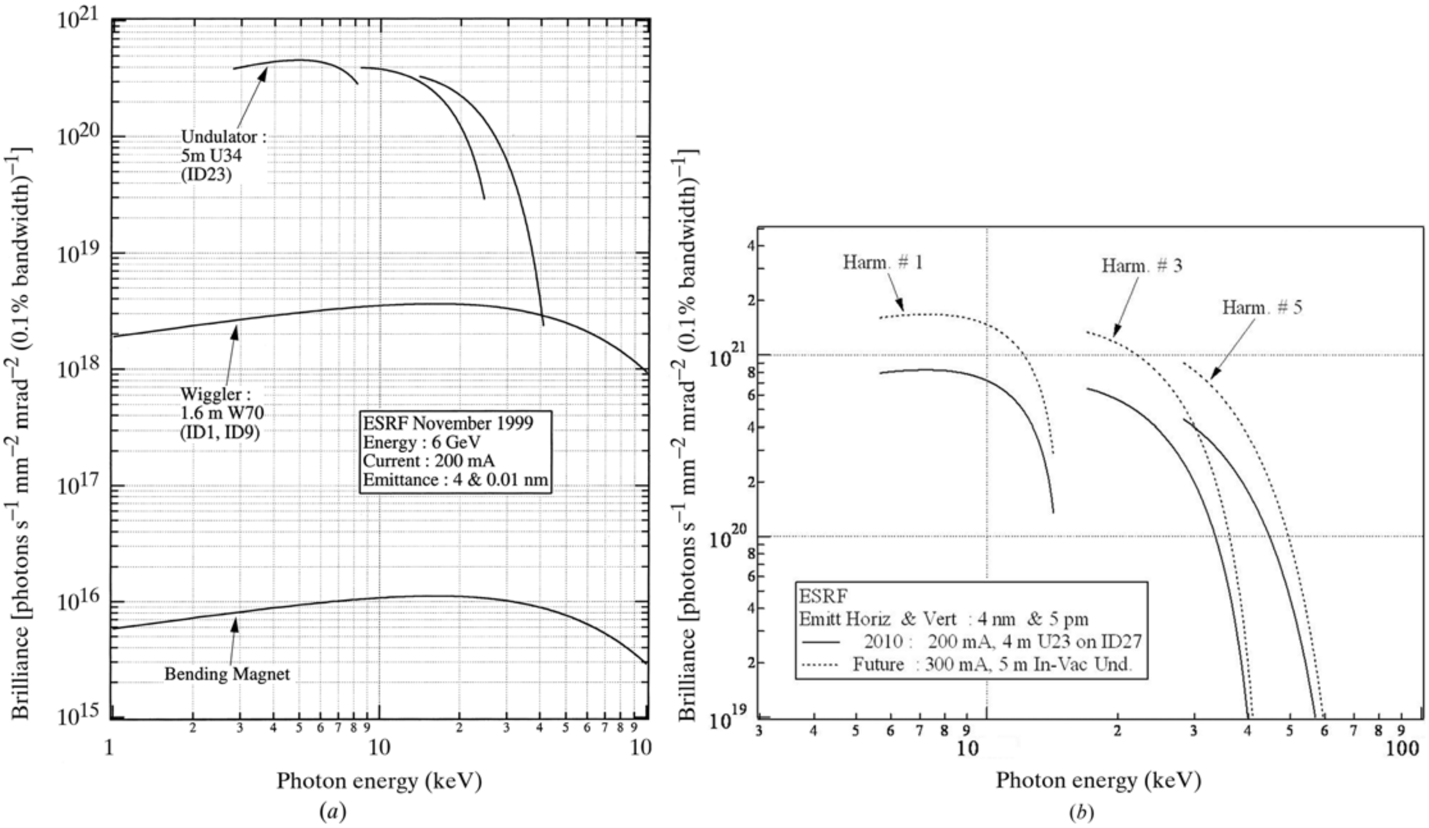

Figure 8.1.2.2

SR spectra. (*a*) Spectral brightness (also referred to as brilliance) of different SR source types (undulator, multipole wiggler and bending magnet) as exemplified by such types of sources at the ESRF. For the undulator, the tuning range (*i.e.* as the magnet gap is changed) is indicated. (*b*) Brilliance produced by the in-vacuum undulator of cell 27 of the ESRF dedicated to high-pressure studies. The plain curve corresponds to the condition in use as of September 2010. Further increase in brilliance (dotted curve) is expected in the years to come by increasing the ring current, increasing the length of the undulator and further decreasing the vertical emittance. Kindly provided by Dr Pascal Elleaume, ESRF, Grenoble, France.

units, are so ensconced in the field 'that a drive to change this would only lead to more confusion rather than more clarity in the descriptions of synchrotron-radiation sources'. At the ESRF the term brilliance is firmly ensconced in house and with its large user community, and so is the label for the *y* axes used in Fig 8.1.2.2.

Another useful term is the machine emittance, ε. This is an invariant for a given machine lattice and electron/positron machine energy. It is the product of the divergence angle, σ', and the source size, σ:

$$\varepsilon = \sigma\sigma'. \qquad (8.1.2.2)$$

The horizontal and vertical emittances need to be considered separately.

The total radiated power, Q (kW), is expressed in terms of the machine energy, E (GeV), the radius of curvature of the orbiting electron/positron beam, ρ (m), and the circulating current, I (A), as

$$Q = 88.47E^4I/\rho. \qquad (8.1.2.3)$$

The opening half-angle of the synchrotron radiation is $1/\gamma$ and is determined by the electron rest energy, mc^2, and the machine energy, E:

$$\gamma^{-1} = mc^2/E. \qquad (8.1.2.4)$$

The basic spectral distribution is characterized by the universal curve of synchrotron radiation, which is the number of photons per s per A per GeV per horizontal opening in mrad per 1% $\delta\lambda/\lambda$ integrated over the vertical opening angle, plotted versus λ/λ_c. Here the critical wavelength, λ_c (Å), is given by

$$\lambda_c = 5.59\rho/E^3, \qquad (8.1.2.5)$$

again with ρ in m and E in GeV. Examples of SR spectral curves are shown in Fig. 8.1.2.2(*a*). The peak photon flux occurs close to λ_c, the useful flux extends to about $\lambda_c/10$, and exactly half of the total power radiated is above the critical wavelength and half is below this value.

In the plane of the orbit, the beam is essentially 100% plane polarized. This is what one would expect if the electron orbit was visualized edge-on. Away from the plane of the orbit there is a significant (several per cent) perpendicular component of polarization. Schiltz & Bricogne (2009) advocated definitions to use in the analysis of polarization-dependent phenomena that are instrument-independent and completely general. They have implemented these methods in the macromolecular phasing program *SHARP* for exploiting the polarization anisotropy of anomalous scattering in protein crystals.

8.1.3. Insertion devices (IDs)

These are multipole magnet devices placed (inserted) in straight sections of the synchrotron or storage ring. They can be designed to enhance specific characteristics of the SR, namely

(1) to extend the spectral range to shorter wavelengths (wavelength shifter);
(2) to increase the available intensity (multipole wiggler);
(3) to increase the spectral brightness *via* interference and also yield a quasi-monochromatic beam (undulator) (Fig. 8.1.2.2*b* shows the distinctly different emission from an undulator);

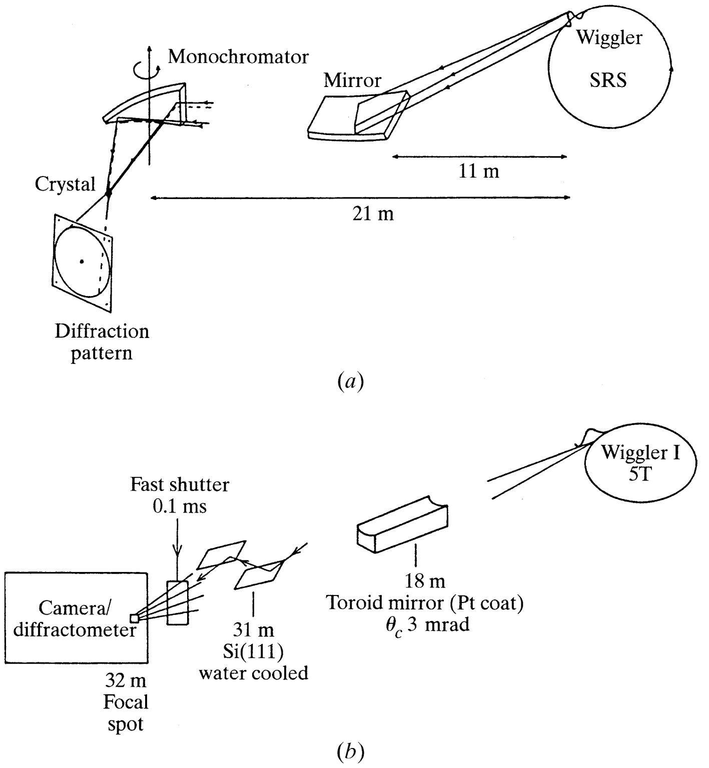

Figure 8.1.4.1
Common beamline optics modes. (*a*) Horizontally focusing cylindrical monochromator and vertical focusing mirror [shown here for station 9.6 as existed at the SRS (adapted from Helliwell *et al.*, 1986)]. (*b*) Rapidly tunable double-crystal monochromator and point-focusing toroid mirror [shown here as existed for station 9.5 at the SRS (adapted from Brammer *et al.*, 1988)].

(4) to provide a different polarization (*e.g.* to rotate the plane of polarization, to produce circularly polarized light *etc.*).

The classification of a periodic magnet ID as a wiggler or undulator is based on whether the angular deflection, δ, of the electron beam is small enough to allow radiation emitted from one pole to interfere directly with that from the next pole. In a wiggler, $\delta \gg \gamma^{-1}$, so the interference is negligible and the spectral emission (Fig. 8.1.2.2*a*) is very similar in shape to, but scaled up from, the universal curve (*i.e.* bending magnet spectral shape). In an undulator $\delta \leq \gamma^{-1}$ and the interference effects are highly significant (Fig. 8.1.2.2*b*). If the period of the ID is λ_u (cm), then the wavelengths λ_i (i integer) emitted are given by

$$\lambda_i = \frac{\lambda_u}{i2\gamma^2}\left(1 + \frac{K^2}{2} + \gamma^2\theta^2\right), \qquad (8.1.3.1)$$

where $K = \gamma\delta$.

The spectral width of each peak is

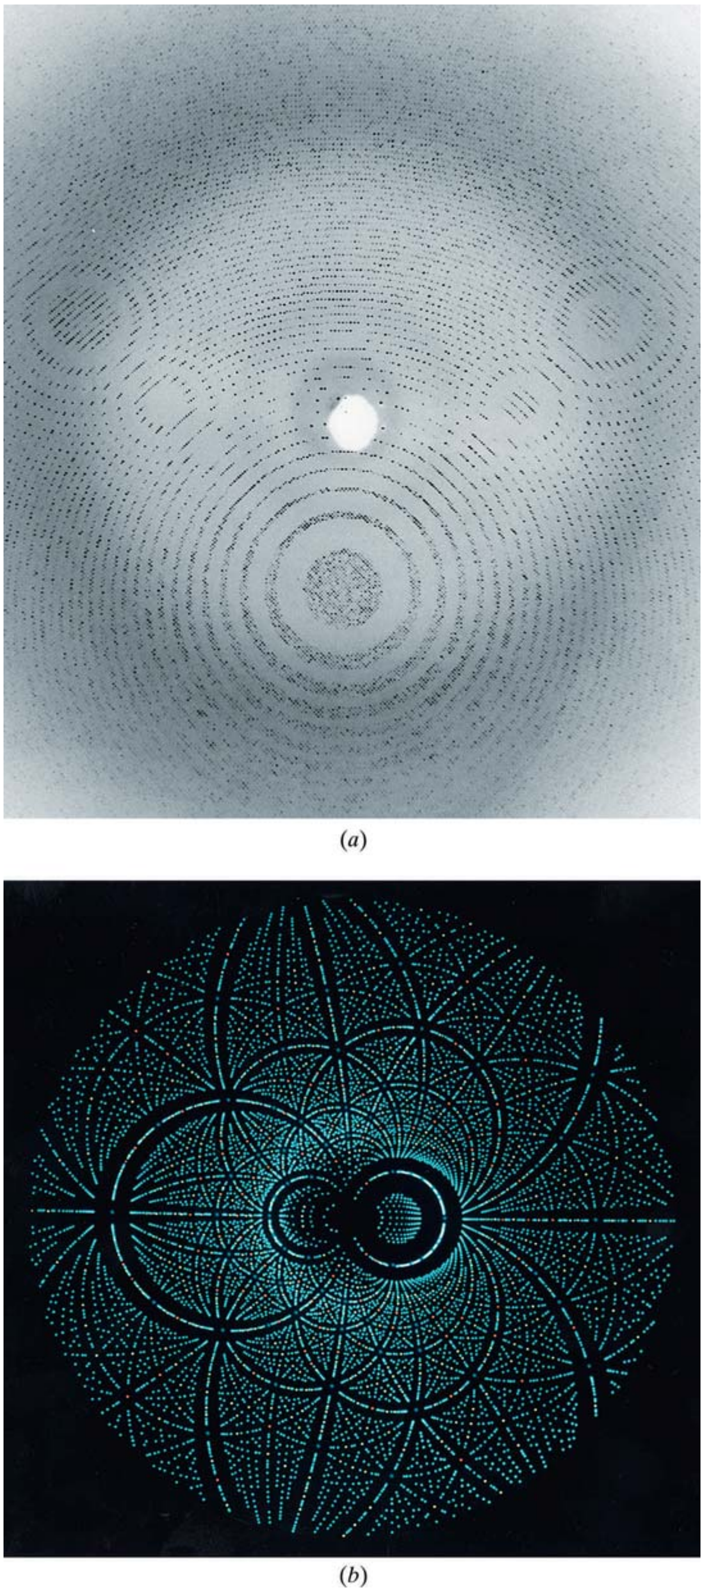
$$\Delta_i \simeq 1/iN, \qquad (8.1.3.2)$$

where N is the number of poles. The angular deflection, δ, is changed by opening or closing the gap between the pole pieces.

8.1.4. Beam characteristics delivered at the crystal sample

The sample acceptance, α [equation (8.1.4.1)], is a quantity to which the synchrotron machine emittance [equation (8.1.2.2)] should be matched, *i.e.*,

$$\alpha = x\eta, \qquad (8.1.4.1)$$



(*a*)

(*b*)

Figure 8.1.4.2
Single-crystal SR diffraction patterns. (*a*) Rhinovirus monochromatic oscillation photograph recorded at CHESS (Arnold *et al.* 1987; see also Rossmann & Erickson, 1983). (*b*) Prediction of a protein crystal Laue diffraction pattern (for an illuminating bandpass, without monochromator, $\sim 0.4 < \lambda < 2.6$ Å). The colour coding is according to the multiplicity of each spot: turquoise for singlet reflections, yellow for doublets, orange for triplets and blue for quartet or higher-multiplicity Laue spots (Cruickshank *et al.*, 1991).

where x is the sample size and η the mosaic spread. For example, if $x = 0.1$ mm and $\eta = 1$ mrad (0.057°), then $\alpha = 10^{-7}$ m rad or 100 nm rad.

At the sample position, the intensity of the beam, usually focused, is a useful parameter:

$$\text{Intensity} = \text{photons per s per focal spot area.} \qquad (8.1.4.2)$$

Moreover, the horizontal and vertical convergence angles are ideally kept smaller than the mosaic spread, *e.g.* ~1 mrad, so as to measure reflection intensities with optimal peak-to-background ratio.

Producing a focal spot area that is approximately the size of a typical crystal (~0.1 mm) and with a convergence angle ~1 mrad sets a sample acceptance requirement to be met by the X-ray beam and machine emittance. A machine with an emittance that matches the acceptance of the sample greatly assists the simplicity and performance of the beamline optics (mirror and/or monochromator) design. The common beamline optics schemes are shown in Fig. 8.1.4.1.

In addition to the focal spot area and convergence angles, it is necessary to provide the appropriate spectral characteristics. In monochromatic applications, involving the rotating-crystal diffraction geometry, for example, a particular wavelength, λ, and narrow spectral bandwidth, $\delta\lambda/\lambda$, are used. Fig. 8.1.4.2(*a*) shows an example of a monochromatic oscillation diffraction photograph from a rhinovirus crystal as an example recorded at CHESS, Cornell. Fig. 8.1.4.2(*b*) shows the prediction of a white-beam broad-band Laue diffraction pattern from a protein crystal that was recorded at the SRS wiggler, Daresbury, colour-coded for multiplicity.

Table 8.1.4.1 lists the internet addresses of the SR facilities worldwide that currently have macromolecular beamlines. A considerable suite of information on SR and free electron laser (FEL) sources can also be found at http://www.lightsources.org/cms/. Comprehensive statistics for the macromolecular crystal structures from all the various beamlines over the years can be obtained at http://biosync.rcsb.org/.

8.1.5. Evolution of SR machines and experiments

8.1.5.1. First-generation SR machines

The so-called first generation of SR machines were those which were parasitic on high-energy physics operations, such as DESY in Hamburg, SPEAR in Stanford, NINA in Daresbury and VEPP in Novosibirsk. These machines had high fluxes into the X-ray range and enabled pioneering experiments. Parratt (1959) discussed the use of the CESR (Cornell Electron Storage Ring) for X-ray diffraction and spectroscopy in a very perceptive paper. Cauchois *et al.* (1963) conducted *L*-edge absorption spectroscopy at Frascati and were the first to diffract SR with a crystal (quartz). The opening experimental work in the area of biological diffraction was by Rosenbaum *et al.* (1971). In protein crystallography, multiple-wavelength anomalous-dispersion effects (Fig.

8.1.5.1) were used from the onset (Phillips *et al.*, 1976, 1977; Phillips & Hodgson, 1980; Webb *et al.*, 1977; Harmsen *et al.*, 1976; Helliwell, 1977, 1979), and a reduction in radiation damage was seen for high-resolution data collection (Wilson *et al.*, 1983). Historical insights into the performances of those machines, from the current-day perspective, are described in detail, for example, by Huxley & Holmes (1997) at DESY, Munro (1997) at Daresbury, and Doniach *et al.* (1997) at Stanford. A principal limitation was the problem of source movements, which degraded the focusing of the source onto a small crystal or single fibre and thus degraded the intrinsic spectral brightness of the beam; see, for example, Haslegrove *et al.* (1977), who advocated machine shifts dedicated to SR as a working compromise with the high-energy physicists. Some possible applications that were discussed were unfulfilled until brighter sources became available. The two-wavelength crystallography phasing method of Okaya & Pepinsky (1956) (see also Hoppe & Jakubowski, 1975) and the three-wavelength method of Herzenberg & Lau (1967), as well as the implementation of the algebraic method of Karle (1967, 1980, 1989, 1994), awaited more stable beams, which had to be rapidly and easily tunable over a fine bandpass (ideally 10^{-4}). Experiments to define the anomalous-dispersion coefficients, including dichroism effects, at a large number of wavelengths at several example absorption edges in a variety of crystal structures were conducted at SPEAR (Phillips *et al.*, 1978; Templeton *et al.*, 1980, 1982; Templeton & Templeton, 1985). Large values of f'' were identified at 'white lines', *i.e.* regions of the elemental absorption with pronounced effects (*e.g.* see Fig 8.1.5.1*a*). Values of f' over a continuum of wavelengths in a real compound (*i.e.*, not a metal in the gas phase) (Fig. 8.1.5.1*b*) were explored in a profile approach (now called DAFS, diffraction anomalous fine structure) by Arndt *et al.* (1982) at the newly commissioned SRS, the first dedicated second-generation SR source (see Section 8.1.5.2).

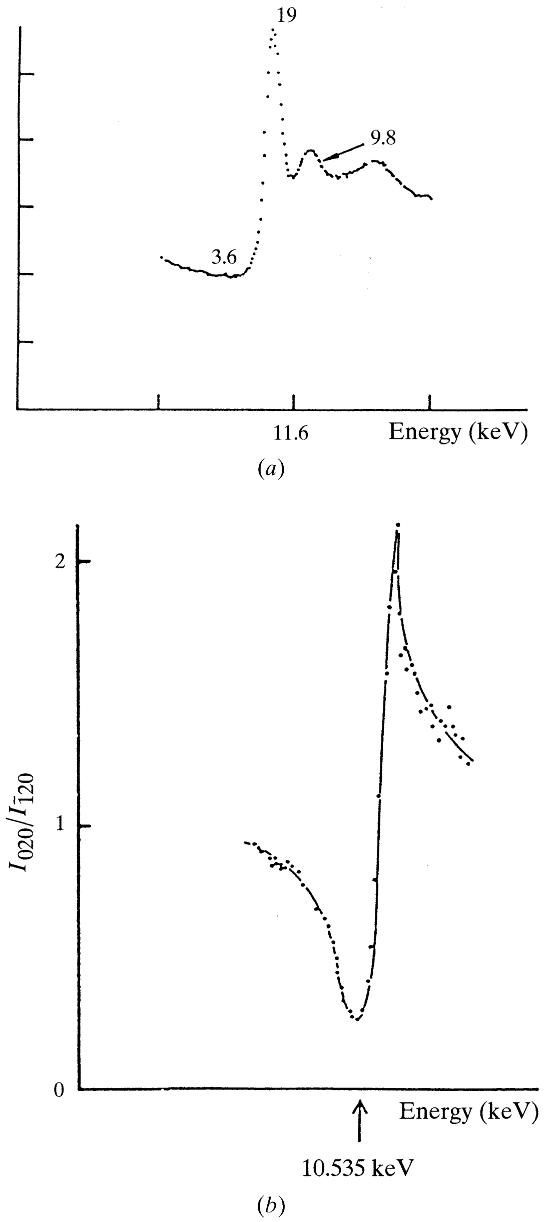

Figure 8.1.5.1
Anomalous dispersion. (*a*) f'' as represented by an absorption spectrum [Pt L_{III} edge for $K_2Pt(CN)_4$ as the example with 19 electrons for f'' at the peak of that 'white line', with pre-edge and post-edge f'' electron values also indicated] (Helliwell, 1984). Reproduced with the permission of the Institute of Physics. (*b*) f' as estimated by a continuous polychromatic profile method. Reproduced with permission from *Nature* (Arndt *et al.*, 1982). Copyright (1982) MacMillan Magazines Limited.

8.1.5.2. *Second-generation dedicated machines*

The building of dedicated X-ray sources began with the SRS at Daresbury, which came online in 1980, having followed the NINA synchrotron (closed in 1976) and the associated Synchrotron Radiation Facility at Daresbury. Elsewhere in the world, LURE (Lemonnier *et al.*, 1978) and CHESS at Cornell were building up their SR macromolecular crystallography operations in the late 1970s and early 1980s, and the NSLS in Brookhaven and the Photon Factory (PF) in Japan were both under construction. The NSLS and the PF came online in 1983 and 1984, respectively. Thus, there was a rapid increase in the number of operating machines and beamlines worldwide in the X-ray region for protein crystallography. There were teething problems with the SRS with the radio-frequency cavity window problem, interrupting operation for many months in 1983, and at the NSLS in its early period due to vacuum-chamber problems. Pioneering experiments continued and blossomed. Seminal work ensued in virus crystallography [Rossmann & Erickson (1983) at Hamburg and Daresbury; and Usha *et al.* (1984) at LURE], Laue diffraction for time-resolved protein crystallography [Moffat *et al.* (1984) at CHESS; Helliwell (1984, 1985) at the SRS; Cruickshank *et al.* (1987, 1991); Hajdu, Machin *et al.* (1987); Helliwell *et al.* (1989); Bourenkov *et al.* (1996); Neutze & Hajdu (1997)], enzyme catalysis in the crystal [Hajdu, Acharya *et al.* (1987) at the SRS], MAD [Phillips *et al.* (1977); Einspahr *et al.* (1985); Hendrickson (1985); Hendrickson *et al.* (1989) at SPEAR, the SRS and the PF; Guss *et al.* (1988) at SPEAR; Kahn *et al.* (1985) at LURE; Korszun (1987) at CHESS; Mukherjee *et al.* (1989) and Peterson *et al.* (1996) at the SRS; Hädener *et al.* (1999) at the SRS and the ESRF, to cite a few experiments], protein crystallography involving isomorphous replacement with optimized anomalous scattering [Baker *et al.* (1990) at the SRS; Dumas *et al.* (1995) at LURE], small crystals [Hedman *et al.* (1985) at the SRS] and diffuse scattering with SR [Doucet & Benoit (1987); Caspar *et al.* (1988); Glover *et al.* (1991)]. Table 8.1.5.1 shows the impact of the SRS in protein (*i.e.* macromolecular) crystallography integrated over its whole lifetime.

8.1.5.3. *Third-generation high spectral brightness machines*

As early as 1979, there were discussions on planning a proposal for a high spectral brightness, insertion-device-driven European synchrotron-radiation (ESR) source. A wide variety of discussion

Table 8.1.5.1
Structures in the Protein Data Bank (PDB) for which data were collected at the SRS

The data presented here were compiled in December 2009 (see http://biosync.rcsb.org/biosync_regions/SyncEurope.html#SRS) and are likely to be reasonably complete since the SRS closed operations in August 2008. The SRS has delivered 3.6% of the total of 38 650 macromolecular crystal structures determined using radiation from synchrotrons around the world as of December 2009. The ESRF third-generation source, in comparison, integrated over about half as many years, but about two to three times more beamlines, has delivered 15.6% of the structures, *i.e.* at a rate therefore about three to four times greater than the second-generation SRS.

documents and workshops, and the ESR Project (ESRP) led by B. Buras and based in Geneva at CERN, culminated in the so-called 'Red Book' in 1987, the *ESRF Foundation Phase Report* (1987), totalling some 1000 pages of machine, beamline and experimental specifications and costs. This, then, was the progenitor of the third-generation sources, characterized by their high energy and high spectral brightness, tailored to optimized undulator emission in the 1 Å range. Actually, the ESRF machine energy was initially set at 5 GeV, but increased to 6 GeV to optimize the production of 14.4 keV photons to better match the nuclear scattering experiments proposed initially by Mossbauer in 1975. Proposals for the US machine, the Advanced Photon Source at 7 GeV, and the Japanese 8 GeV SPring-8 machine followed, with the higher machine energy enhancing the X-ray tuning range of undulators. Thus, MAD tuning-based techniques were facilitated with these machines and studies involving yet-smaller samples (crystals, single fibres or tiny liquid aliquots) or very large unit cells were enabled. As a result, micron-sized protein crystals as well as huge multi-macromolecular biological structures (of large viruses, for example) also became routinely accessible.

8.1.5.4. New national SR machines

Today a variety of enhanced national SR machines have been built. In Switzerland there is the SLS, in the UK there is DIAMOND and in France there is SOLEIL. These machines are more tailored to the bulk of a country's user needs, distinct from the special provisions at the ESRF. The different countries' SR needs, of course, have many aspects in common, with some historical biases. The new sources are, in essence, characterized by high spectral brightness, *i.e.*, low emittance. The 2 GeV SR source ELETTRA in Trieste, the MAXII machine in LUND and the Brazilian Light Source are already operational. In many ways, national sources like the SRS, LURE, DORIS and so on fuelled the case and specification for the ESRF. Now the developments at the ESRF, including high harmonic emission of undulators *via* magnet shimming (Elleaume, 1989) and narrow-gap undulator operation (Elleaume, 1998), are fuelling ideas and the specification of what is possible in the new national SR sources.

8.1.5.5. X-ray free-electron lasers (XFELs)

In terms of the evolution of X-ray sources, X-ray FELs are being constructed at DESY in Hamburg (Brinkmann *et al.*, 1997), at SLAC (Winick, 1995) and at Spring8. Compared to SR, one will have a transversely fully coherent beam, a larger average spectral brightness and, in particular, pulse lengths of ~10 fs full width at half-maximum with eight to ten orders of magnitude larger peak spectral brightness. Such a machine is based on a linear accelerator (linac)-driven XFEL utilizing a linear collider installation (*e.g.*, for a high-energy physics centre-of-mass energy capability of 500 GeV). For this machine there is a 'switchyard' distributing the electrons in a beam to different undulators from which the X-rays are generated in the range 0.1 to ~12 keV. The anticipated r.m.s. opening angle would be 1 mrad and the source diameter would be 20 μm. This source of X-rays would then compete in time resolution with laser-pulse-generated X-ray beams [see Helliwell & Rentzepis (1997) for a survey of that work and a comparison with synchrotron radiation] and would also have higher pulse flux. Coherent methods in the X-ray sciences have been extensively reviewed by Nugent (2009).

8.1.6. SR instrumentation

The divergent continuum of X-rays from the source must be intercepted by the sample cross-sectional area. The crystal sample acceptance, as seen above, is a good way to illustrate to the machine designer the sort of machine emittances required. Likewise, the beamline optics, mirrors and monochromators should not degrade the X-ray beam quality. Mirror surface and shape finish have improved a great deal in the last few decades; slope errors of mirrors, even for difficult shapes like polished cylinders, which on bending give a toroidal reflecting surface, are now around 1 arc second (5.5 μrad) for a length of 1 m. Thus, over focusing distances of 10–20 m, say, the focal-spot smearing contribution from this is 55–110 μm, important for focusing onto small crystals. Further optics developments (*e.g.* Fresnel optics) have yielded micron focus beams and smaller, and are being applied to studying ever-smaller crystals in macromolecular crystallography and obviously have a variety of other diffraction and spectroscopy applications [for a review, see Riekel (2000)]. The choice of materials has evolved, too, from the relatively easy-to-work-with and -finish fused quartz to silicon; silicon having the advantageous property that at liquid-nitrogen temperature the expansion coefficient is zero (Bilderback, 1986). This has been of particular advantage in the cooling of silicon monochromators at the ESRF, where the heat loading on optics is very high. An alternative approach with the rather small X-ray beams from undulators is the use of transparent monochromator crystals made of diamond, which is a robust material with the additional advantage of transparency, thus allowing multiplexing of stations, one downstream from the other, fed by one straight section of one or more undulator designs. For a review of the ESRF beamline optics, see Freund (1996); for reviews of the macromolecular crystallography programmes at the ESRF, see Miller (1994), Branden (1994) and Lindley (1999), as well as the *ESRF Foundation Phase Report* (1987). See also Helliwell (1992), Chapter 5.

Detectors have improved enormously. The early days of SR use saw considerable reliance on photographic film, as well as single-counter four-circle diffractometers. Evolution of area detectors, in particular, has been considerable and impressive, and in a variety of technologies. Gas detectors, *i.e.*, the multiwire proportional chamber (MWPC), were invented and developed through various generations and types [Charpak (1970); for reviews of their use at SR sources, see *e.g.* Lewis (1994) and Fourme (1997)]. MWPCs have the best detector quantum efficiency (DQE) of the area detectors, but there are limitations on count rate (local and global) and their use at wavelengths less than ~1 Å is restricted due to geometric image parallax effects. The most popular devices at present are charge coupled devices (CCDs) [see Tate *et al.* (1995), Allinson (1994), Gruner & Ealick (1995) and Westbrook & Naday (1997) for details of their development]. Image plates (IPs) were popular during the late 1980s and early to mid-1990s, mainly, but not exclusively, with online scanners, notably the MAR Research devices. IPs are also used in a Weissenberg geometry [see Sakabe (1983, 1991) and Sakabe *et al.* (1995), and for a recent review see Amemiya (1997)]. IPs and CCDs are complementary in performance, especially with respect to size and duty cycle; IPs are larger, *i.e.*, with many resolution elements possible, but are slower to read out than CCDs. Both are capable of imaging well at wavelengths shorter than 1 Å and with high count rates. Both have overcome the tedium of chemical development of film. Other detectors needed for crystallography include those for monitoring the beam intensity; these must not interfere with the beam collimation, and yet must monitor the beam downstream of the collimator (Bartunik *et al.*, 1981); also needed are fluorescence detectors for setting the wavelength for optimized anomalous-scattering applications (see Cianci *et al.*, 2005).

Most recently, an area-detector development has been the so-called pixel detector. This is made of silicon cells, each 'bump bonded' onto associated individual electronic readout chains. Thus, extremely high count rates are possible. These devices can then combine the attributes of large image plate sensitive areas with the fast readout of CCDs, along with high count-rate capability and so on. Devices and prototypes have been developed at Princeton/Cornell (Eikenberry *et al.*, 1998), Berkeley/San Diego (Beuville *et al.* 1997) and Imperial College, London (Hall, 1995), and are now in use at the SLS (Broennimann *et al.*, 2006).

Provision of robotics for sample mounting on the synchrotron beamlines has been increasingly deployed in the last decade, improving efficiency and ease of use, often coupled with remote access (*e.g.* see Gonzalez *et al.*, 2005) and telepresence (*e.g.* see Warren *et al.*, 2008).

8.1.7. SR monochromatic and Laue diffraction geometry

In the utilization of SR, both Laue and monochromatic modes are important for data collection. The unique geometric and spectral properties of SR render the treatment of diffraction geometry different from that for a conventional X-ray source.

8.1.7.1. Laue geometry: sources, optics, sample reflection bandwidth and spot size

Laue geometry involves the use of the polychromatic SR spectrum as transmitted through the beryllium window that is used to separate the apparatus from the machine vacuum. There is useful intensity down to a wavelength minimum of $\sim\lambda_c/5$, where λ_c is the critical wavelength of the magnet source in the case of bending magnets (BMs) and wavelength shifters. The maximum wavelength is typically ≥ 3 Å; however, if the crystal is mounted in a capillary, then the glass absorbs the wavelengths beyond ~2.5 Å (Helliwell, 2004).

The bandwidth on BMs and wigglers can be limited by a reflecting mirror at grazing incidence, whereby the minimum wavelength in the beam can be sharply defined to aid the accurate definition of the Laue spot multiplicity. The mirror can also be used to focus the beam at the sample. The maximum-wavelength limit can be truncated by use of aluminium absorbers of varying thickness or a transmission mirror (Lairson & Bilderback, 1982; Cassetta *et al.*, 1993).

The measured intensity of individual Laue diffraction spots depends on the wavelength at which they are stimulated. The problem of wavelength normalization is treated by a variety of methods. These include:

(i) use of a monochromatic reference data set;
(ii) use of symmetry equivalents and multiple measurements in the Laue data set recorded at different wavelengths;
(iii) calibration with a standard sample, such as a silicon crystal.

Each of these methods produces a 'λ curve' describing the relative strength of spots measured at various wavelengths. Most Laue diffraction data are now recorded on CCDs or IPs. The greater sensitivity of these detectors (expressed as the DQE), especially for weak signals, has greatly increased the number of Laue exposures recordable per crystal (*e.g.* Nieh *et al.*, 1999). Thus, multiplet deconvolution procedures, based on the recording of reflections stimulated at different wavelengths and with different relative intensities, have become possible (Campbell & Hao, 1993; Ren & Moffat, 1995*b*; Nieh *et al.*, 1999). Data quality and completeness have improved considerably.

Narrow-bandpass beams, *e.g.* $\delta\lambda/\lambda \leq 0.2$, are used for enhancing the signal-to-noise ratio. Such bandwidths are produced generally by an X-ray undulator, whereby *e.g.* 10–100 periods should ideally yield a bandwidth behind a pinhole of $\delta\lambda/\lambda \simeq 0.1$–$0.01$. In these cases, wavelength normalization is more difficult, because the actual spectrum over which a reflection is integrated is rapidly varying in intensity; nevertheless, high-order Chebychev polynomials are successful (Ren & Moffat, 1995*a*; Artz *et al.*, 1999).

The spot bandwidth is determined by the mosaic spread and horizontal beam divergence (since $\gamma_H > \gamma_V$) as

$$(\delta\lambda/\lambda) = (\eta + \gamma_H)\cot\theta, \qquad (8.1.7.1)$$

where η is the sample mosaic spread, assumed to be isotropic, and

γ_H is the horizontal cross-fire angle, which in the absence of focusing is $(x_H + \sigma_H)/P$, where x_H is the horizontal sample size, σ_H is the horizontal source size and P is the sample to the tangent-point distance. This is similar for γ_V in the vertical direction. Generally, at SR sources, σ_H is greater than σ_V. When a focusing-mirror element is used, γ_H and/or γ_V are convergence angles determined by the focusing distances and the mirror aperture.

The size and shape of the diffraction spots vary across the detector image plane. The radial spot length is given by convolution of Gaussians as

$$\left(L_R^2 + L_c^2 \sec^2 2\theta + L_{\rm PSF}^2\right)^{1/2} \qquad (8.1.7.2)$$

and tangentially by

$$\left(L_T^2 + L_c^2 + L_{\rm PSF}^2\right)^{1/2}, \qquad (8.1.7.3)$$

where L_c is the size of the X-ray beam (assumed to be circular) at the sample, $L_{\rm PSF}$ is the detector point-spread factor,

$$L_R = D \sin(2\eta + \gamma_R) \sec^2 2\theta, \qquad (8.1.7.4)$$

$$L_T = D(2\eta + \gamma_T) \sin\theta \sec 2\theta, \qquad (8.1.7.5)$$

and

$$\gamma_R = \gamma_V \cos\psi + \gamma_H \sin\psi, \qquad (8.1.7.6)$$

$$\gamma_T = \gamma_V \sin\psi + \gamma_H \cos\psi, \qquad (8.1.7.7)$$

where ψ is the angle between the vertical direction and the radius vector to the spot (see Andrews *et al.*, 1987). For a crystal that is not too mosaic, the spot size is dominated by L_c and $L_{\rm PSF}$. For a mosaic or radiation-damaged crystal, the main effect is a radial streaking arising from η, the sample mosaic spread.

8.1.7.2. Monochromatic SR beams: optical configurations and sample rocking width

A wide variety of perfect-crystal monochromator configurations are possible and have been reviewed by various authors (Hart, 1971; Bonse *et al.*, 1976; Hastings, 1977; Kohra *et al.*, 1978). Since the reflectivity of perfect silicon and germanium is effectively 100%, multiple-reflection monochromators are feasible and permit the tailoring of the shape of the monochromator resolution function, harmonic rejection and manipulation of the polarization state of the beam. Two basic designs are in common use. These are the bent single-crystal monochromator of triangular shape (Fig. 8.1.4.1*a*) and the double-crystal monochromator (Fig. 8.1.4.1*b*).

8.1.7.2.1. Curved single-crystal monochromator

In the case of the single-crystal monochromator, the actual curvature employed is very important in the diffraction geometry. For a point source and a flat monochromator crystal, there is a gradual change in the photon wavelength selected from the white beam as the length of the monochromator is traversed (Fig. 8.1.7.1*a*). For a point source and a curved monochromator crystal, one specific curvature can compensate for this variation in incidence angle (Fig. 8.1.7.1*b*). The reflected spectral bandwidth is then at a minimum; this setting is known as the 'Guinier position'. If the curvature of the monochromator crystal is increased further, a range of photon wavelengths, $(\delta\lambda/\lambda)_{\rm corr}$, is selected along its length so that the rays converging towards the focus have a correlation of photon wavelength and direction (Fig. 8.1.7.1*c*). The effect of a finite source is to cause a change in incidence angle at the monochromator crystal, so that at the focus there is a photon-wavelength gradient across the width of the focus (for all curvatures) (Fig. 8.1.7.1*d*). The use of a slit in the focal plane is akin to placing a slit at the tangent point to limit the source size.

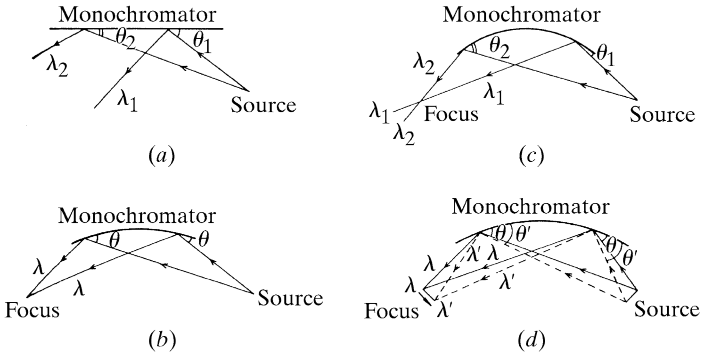

Figure 8.1.7.1

8.1.7.2.2. Double-crystal monochromator

The double-crystal monochromator with two parallel or nearly parallel perfect crystals of germanium or silicon is a common configuration. The advantage of this is that the outgoing monochromatic beam is parallel to the incoming beam, although it is slightly displaced vertically by an amount $2d\cos\theta$, where d is the perpendicular distance between the crystals and θ is the monochromator Bragg angle (unless the second crystal is unconnected to the first, in which case it can be translated as well to compensate for that). The monochromator can be rapidly tuned, since the diffractometer or camera need not be re-aligned significantly in a scan across an absorption edge. Since the rocking width of the fundamental is broader than the harmonic reflections, the strict parallelism of the pair of the crystal planes can be 'detuned', so that the harmonic can be rejected with little loss of the fundamental intensity. The spectral spread in the reflected monochromatic beam is determined by the source divergence accepted by the monochromator, the angular size of the source and the monochromator rocking width (see Fig. 8.1.7.2). The double-crystal monochromator is often used with a toroidal focusing mirror; the functions of monochromatization are then separated from the focusing (Hastings *et al.*, 1978).

8.1.7.2.3. Widening of monochromatic wavelength range provision

Users and facilities have been driven to use an ever-widening practical range of X-ray wavelengths. Longer wavelengths in protein crystallography have been explored up to 2.6 Å (Helliwell, 1993, 1997*a*, 2004; Polikarpov *et al.*, 1997; Teplyakov *et al.*, 1998; Cianci *et al.*, 2001, 2008), and even softer wavelengths have been under active development to utilize the uranium M edge at 3.326 and 3.490 Å (Liu *et al.*, 2001), and the S K edge for anomalous dispersion (Stuhrmann & Lehmann, 1994). At very short (~0.5 Å) and ultra-short (~0.3 Å) wavelengths, a high machine energy yields copious flux output; pilot studies have been conducted in protein crystallography at CHESS (Helliwell *et al.*, 1993), at the ESRF (Schiltz *et al.*, 1997) and at the NSLS (Jakoncic *et al.*, 2006). Notably Fourme and colleagues have exploited the condensed angular distribution of the diffraction pattern at such wavelengths to pass the beam through the narrow

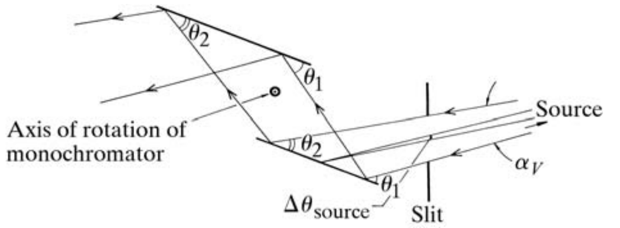

Figure 8.1.7.2
Double-crystal monochromator illuminated by SR. The contributions of the source divergence, α_V [less than or equal to γ^{-1}, equation (8.1.2.4), depending on the monochromator vertical entrance slit aperture; see also Colapietro *et al.* (1992)], and angular source size, $\Delta\theta_{\rm source}$, to the range of energies reflected by the monochromator are shown. From Helliwell (1984). Reproduced with the permission of the Institute of Physics.

exit window of a high-pressure cell for protein-crystal high-pressure biophysical studies (Fourme *et al.*, 2001; Girard *et al.*, 2007). Such developments interact closely with machine and beamline specifications.

8.1.7.2.4. Crystal sample rocking width

The rocking width of a reflection depends on the horizontal and vertical beam divergence or convergence (after due account for collimation is taken), γ_H and γ_V, the spectral spreads $(\delta\lambda/\lambda)_{\rm conv}$ and $(\delta\lambda/\lambda)_{\rm corr}$, and the mosaic spread, η. We assume that the mosaic spread η is $\gg \omega$, the angular broadening of a reciprocal-lattice point (relp) due to a finite sample. In the case of synchrotron radiation, γ_H and γ_V are usually widely asymmetric. On a conventional source, usually $\gamma_H \simeq \gamma_V$. Two types of spectral spread occur with synchrotron (and neutron) sources. The term $(\delta\lambda/\lambda)_{\rm conv}$ is the spread that is passed down each incident ray in a divergent or convergent incident beam; the subscript refers to the conventional source type. This is because it is similar to the $K\alpha_1, K\alpha_2$ line widths and separation. At the synchrotron, this component also exists and arises from the monochromator rocking width and finite-source-size effects. The term $(\delta\lambda/\lambda)_{\rm corr}$ is special to the synchrotron or neutron case. The subscript 'corr' refers to the fact that the ray direction can be correlated with the photon or neutron wavelength. In this most general case, and for one example of a $(\delta\lambda/\lambda)_{\rm corr}$ arising from the horizontal ray direction correlation with photon energy and the case of a horizontal rotation axis, the rocking width φ_R of an individual reflection is given by

$$\varphi_R = \left\{L^2\left[(\delta\lambda/\lambda)_{\rm corr}d^{*2} + \zeta\gamma_H\right]^2 + \gamma_V^2\right\}^{1/2} + 2\varepsilon_s L, \qquad (8.1.7.8)$$

where

$$\varepsilon_s = (d^*\cos\theta/2)\left[\eta + (\delta\lambda/\lambda)_{\rm conv}\tan\theta\right] \qquad (8.1.7.9)$$

and L is the Lorentz factor, $1/\left(\sin^2 2\theta - \zeta^2\right)^{1/2}$.

The Guinier setting of an instrument (curved crystal monochromator case, Fig. 8.1.7.1*b*) gives $(\delta\lambda/\lambda)_{\rm corr} = 0$. The equation for φ_R then reduces to

$$\varphi_R = L\left[\left(\zeta^2\gamma_H^2 + \gamma_V^2/L^2\right)^{1/2} 2\varepsilon_s\right] \qquad (8.1.7.10)$$

(from Greenhough & Helliwell, 1982). For example, for $\zeta = 0$, $\gamma_V = 0.2$ mrad (0.01°), $\theta = 15°$, $(\delta\lambda/\lambda)_{\rm conv} = 1 \times 10^{-3}$ and $\eta = 0.8$ mrad (0.05°), then $\varphi_R = 0.08°$. But φ_R increases as ζ increases [see Greenhough & Helliwell (1982), Table 5]. In the rotation/oscillation method as applied to protein and virus crystals, a small angular range is used per exposure. For example, the maximum rotation range per image, $\Delta\varphi_{\max}$, may be 1.5° for a protein and 0.4° or so for a virus. Many reflections will be only partially stimulated over the exposure. It is important, especially in the virus case, to predict the degree of penetration of the relp through the Ewald sphere. This is done by analysing the interaction of a spherical volume for a given relp with the Ewald sphere. The radius of this volume is given by

$$E \simeq \varphi_R/2L \qquad (8.1.7.11)$$

(Greenhough & Helliwell, 1982).

Figure 8.1.7.3
The rocking width of an individual reflection for the case of Fig. 8.1.7.1(*c*) and a vertical rotation axis. From Greenhough & Helliwell (1982).

In Fig. 8.1.7.3, the relevant parameters are shown. The diagram shows $(\delta\lambda/\lambda)_{\rm corr} = 2\delta$ in a plane, usually horizontal with a perpendicular (vertical) rotation axis, whereas the formula for φ_R above is for a horizontal axis. This is purely for didactic reasons since the interrelationship of the components is then much clearer.

The limits of protein-crystal rocking widths have been explored by Helliwell (1988), Colapietro *et al.* (1992) and Snell (1995), whereby arc-second crystal precision has been observed at room temperature, *i.e.* unfrozen protein crystals. Special analysis software (Lovelace *et al.*, 2000) has been written to extract such precise crystal mosaicity values and the experiment obviously requires stringent (usually undulator) collimation. Exact comparisons of mosaicity values need reflection indexing, *e.g.* see Snell *et al.* (1995).

8.1.8. Scientific utilization of SR in protein crystallography

There are a myriad of applications and results of the use of SR in crystallography. Helliwell (1992) gave an extensive survey and tabulations of SR and macromolecular crystallography applications; Chapter 9 therein concentrates on anomalous scattering and Chapter 10 on high resolution, large unit cells, small crystals, weak scattering efficiency and time-resolved data collection. The field has expanded so dramatically, in fact, that an equivalent survey today would be vast. Table 8.1.4.1 lists the web pages of the facilities, where the specifications and details of the beamlines can be found (*e.g.* all the publications at Daresbury in the protein crystallography area organized by beamline instrument are to be found at http://dlwebres.dl.ac.uk/dl_public/publications/index.jsp). The examples below cite extreme cases of the large unit cell (virus and multi-macromolecular) cases, weak anomalous-scattering signal in MAD, fast time-resolved Laue

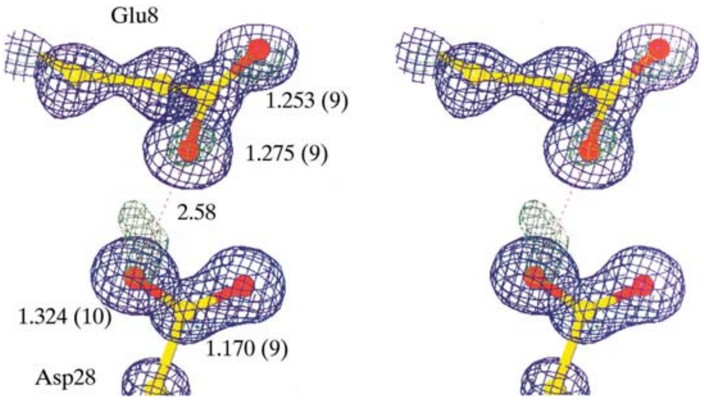

Figure 8.1.8.1
Determination of the protonation states of carboxylic acid side chains in proteins *via* hydrogen atoms and resolved single and double bond lengths. After Deacon *et al.* (1997) using CHESS. Reproduced by permission of The Royal Society of Chemistry.

studies and the ultra-high-resolution and even valence-density structure determinations to date. Another phasing technique involving multiple (‘*n*-beam’) diffraction is also being applied to proteins [Weckert & Hümmer (1997) at the ESRF and the NSLS]. These examples at least indicate the present bounds of capability of the various sub-fields of SR and macromolecular crystallography.

8.1.8.1. Atomic and ultra-high-resolution macromolecular crystallography

The use of high SR intensity, cryo-freezing of a protein crystal to largely overcome radiation damage and sensitive, automatic area detectors (CCDs and/or image plates) is allowing diffraction data to be recorded at resolutions equivalent to smaller-molecule (chemical) crystallography. In a growing number of protein crystal structure studies, atomic resolution (1.2 Å or better) is achievable (Dauter *et al.*, 1997). The ‘X-ray data to parameter’ ratio can be favourable enough for single and double bonds, *e.g.* in carboxyl side chains, to be resolved [Fig. 8.1.8.1; Deacon *et al.* (1997) for concanavalin A at 0.94 Å resolution]. Along with this bond-distance precision, one can see the reactive proton directly. This approach complements H/D exchange neutron diffraction studies. Neutron studies have expanded in scope by employing Laue geometry in a synergistic development with SR Laue diffraction (Helliwell & Wilkinson, 1994; Helliwell, 1997*b*; Habash *et al.*, 1997, 2000); a comprehensive survey of neutron macromolecular crystallography, instruments and results in determining the atomic details of protonation and hydration has been given by Blakeley (2009). In particularly well ordered protein structure cases, valence-electron-density descriptions are possible for those atoms with *B* factors ~<3 Å^2 [see *e.g.* Guillot *et al.* (2008) and Luger (2007)]. The scope and accuracy of protein crystal structures has been transformed. A diffraction-component precision index for characterizing the overall precision of protein structures has been given by Cruickshank (1999) and cast in terms of experimental parameters by Blow (2002).

8.1.8.2. Small crystals

Compensating for small crystal sample volume by increasing the intensity at the sample has been of major interest from the outset, and tests showed that the use of ~20 µm-sized samples is feasible (Hedman *et al.*, 1985). Third-generation high spectral brightness sources were optimized for this application *via* micron-sized focal spot beams, as described in the *ESRF Foundation Phase Report* (1987). Applications of the ESRF microfocus beamline diffractometer (Perrakis *et al.*, 1999) include as an example the determination of the structure of the bacteriorhodopsin crystal at high resolution from micro-crystals (Pebay-Peyroula *et al.*, 1997). Experiments using extremely thin plates involving only 1000 protein molecular layers are described by Mayans & Wilmanns (1999) on the BW7B wiggler beamline at DESY, Hamburg. A variety of small crystals and SR, including tabulated sample scattering efficiencies, can be found in Helliwell (1992), pp. 410–414 and more recently in Riekel *et al.* (2005). The ESRF Upgrade (Fig 8.1.2.2) will push this into the sub-micron territory.

8.1.8.3. Time-resolved macromolecular crystallography

Time-resolved SR Laue diffraction of light-sensitive proteins, such as CO Mb studied with sub-nanosecond time resolution in pump–probe experiments (see Srajer *et al.*, 1996), have shown direct structural changes as a function of time. Enzymes, likewise, are being studied directly by time-resolved methods *via* a variety of reaction initiation methods, including pH jump, substrate diffusion and light flash of caged compounds pre-equilibrated in the crystal. Flash freezing is increasingly used to trap molecular structures at optimal times in a reaction determined either by microspectrophotometry or repeated Laue ‘flash photography’. Enzyme reaction rates can be altered through site-directed mutagenesis (*e.g.* see Niemann *et al.*, 1994; Helliwell *et al.*, 1998) and matched to diffraction-data acquisition times. For overviews, see the books edited by Cruickshank *et al.* (1992) and Helliwell & Rentzepis (1997), the recent review by Bourgeois & Weik (2009) and the companion chapter by Moffat (Chapter 8.2 in this volume).

8.1.8.4. Multi-macromolecular complexes

There is now a wealth of results in this field and the reader must be referred to books such as Liljas *et al.* (2009) for a detailed exposition. Multi-macromolecular complexes, such as viruses (Rossmann *et al.*, 1985; Acharya *et al.*, 1989; Liddington *et al.*, 1991) (Fig. 8.1.8.2), the nucleosome (Luger *et al.*, 1997), light-harvesting complex (McDermott *et al.*, 1995) and the 13-subunit membrane-bound protein cytochrome *c* oxidase (Tsukihara *et al.*, 1996), and large-scale molecular assemblies like muscle (Holmes, 1998) are very firmly recognizable as biological entities whose crystal structure determinations relied on SR. These single-crystal structure determinations involved extremely large unit cells and became tractable despite very weak scattering strength. The crystals often showed extreme sensitivity to radiation (hundreds, even a thousand, crystals have been used to constitute a single data set). Cryocrystallography radiation protection is now used extensively in crystallographic data collection and was critical for work with ribosome crystals (Hope *et al.*, 1989); SR has been essential for these structure determinations (see *e.g.* Yonath, 1992; Yonath *et al.*, 1998; Ban *et al.*, 1998; Wimberley *et al.*, 2000; Noller, 2005). A very large multi-protein complex solved using data from the Daresbury SRS wiggler is the F$_1$ ATPase structure (Fig. 8.1.8.3), for which a share in the Nobel Prize for Chemistry in 1997 was awarded to John Walker in Cambridge. The structure (Abrahams *et al.*, 1994; Abrahams & Leslie, 1996) and the amino-acid sequence data, along with fluorescence microscopy, show how biochemical energy is harnessed to drive the proton pump across biological membranes, thus corroborating hypotheses about this process made over many years. This

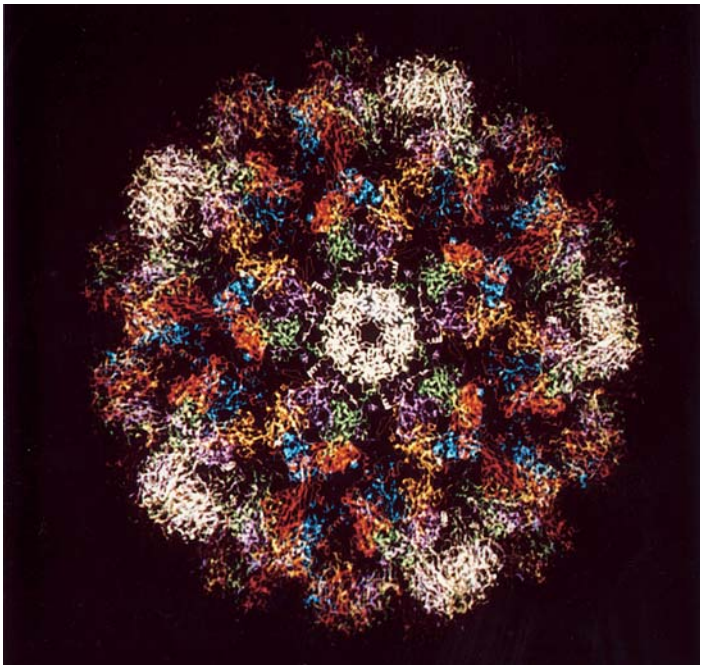

Figure 8.1.8.2
A view of SV40 virus (based on Liddington *et al.*, 1991) determined using data recorded at the SRS wiggler station 9.6 (Fig. 8.1.4.1*a*).

study, made tractable by the SRS wiggler high-intensity protein crystallography station (Fig. 8.1.4.1), illustrates the considerable further scope that became possible with third-generation SR sources, such as the 780 Å diameter blue tongue virus (Grimes *et al.*, 1997, 1998) and the nucleosome core particle (Luger *et al.*, 1997). Spectacular progress has been made in the structural biology of photosynthesis using SR sources, which is not only yielding answers on this vital natural process but also stimulating much research to help address artificial energy sources based on this natural system. This research could have profound climate-change impacts with 'greener energy sources'. One such structure is the Photosystem II (PSII; see Fig. 8.1.8.4). This topic has been reviewed recently by Barber (2009); the atomic details of the Mn$_4$Ca cluster of PSII have proved to be especially challenging to X-ray study (Yano *et al.*, 2005). These large-scale molecular assemblies often combine electron-microscope and diffraction techniques with SR X-ray crystallography and diffraction for low-to-high resolution detail, respectively.

8.1.8.5. Optimized anomalous dispersion (MAD), improved multiple isomorphous replacement (MIR) data and 'structural genomics'

Rapid protein structure determination *via* the MAD method, notably involving seleno protein variants (Hendrickson *et al.*, 1990) as well as xenon pressure derivatives (see *e.g.* Schiltz *et al.*, 1997; Cianci *et al.*, 2001), and improved heavy-atom isomorphous replacement data are removing a major bottleneck in protein crystallography: that of phase determination. Databases of successful heavy-atom compounds (see *e.g.* Sugahara *et al.*, 2009) have been compiled and are increasingly sophisticated. Overall, as the number of protein structures in the Protein Data Bank doubles every few years, the possibility of considering whole genome-level structure determinations arises (Chayen *et al.*, 1996; Chayen & Helliwell, 1998). The human genome comprises some 35 000 genes. Of these, some 40% are coding for membrane-bound proteins, which are more difficult to crystallize. Since a MAD protein crystal structure currently requires less than 1 day of SR BM beamtime, the new 'bottlenecks' are protein production and crystallization. Thus, structural genomics projects have established 'pipelines' for protein structure determination with a view to creating a complete 'protein folds space'. This approach, along with homology modelling and genetic alignment techniques, opens the immense potential for structural genomics to yield huge numbers of experimentally derived protein structures and thereby a much better basis for understanding and controlling disease through structure-based drug design and

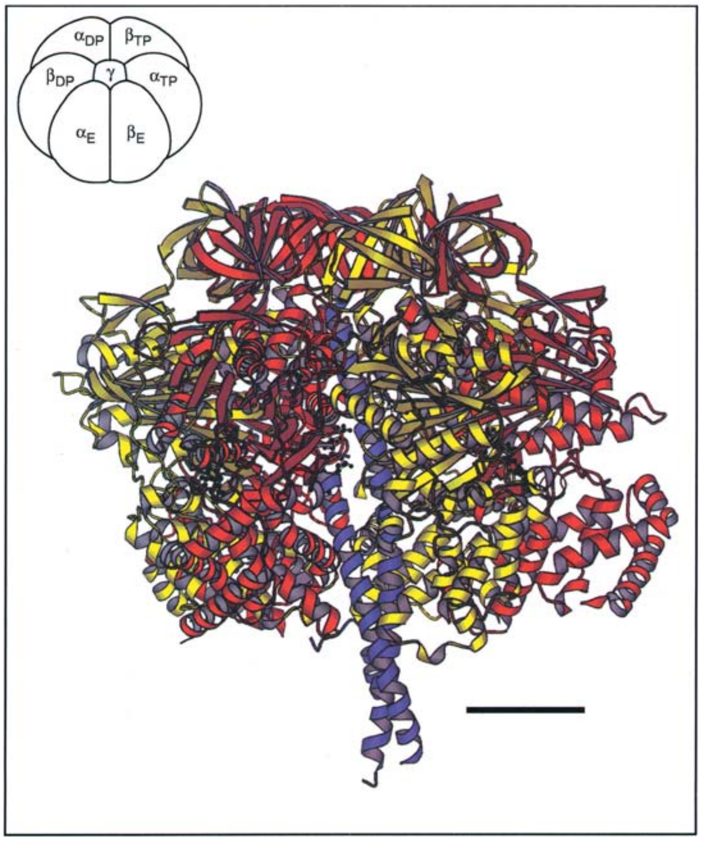

Figure 8.1.8.3
The protein crystal structure of F$_1$ ATPase, one of the largest non-symmetrical protein structure complexes, solved using SR data recorded on an image plate at the SRS wiggler 9.6, Daresbury. The scale bar is 20 Å long. Reprinted with permission from *Nature* (Abrahams *et al.*, 1994). Copyright (1994) MacMillan Magazines Limited.

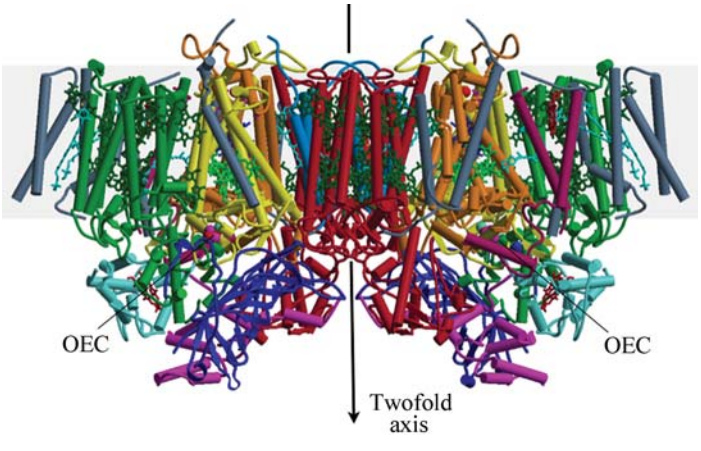

Figure 8.1.8.4
Side view of the structure of Photosystem II, the water-splitting enzyme of photosynthesis, determined using X-ray crystallography based on data recorded at the SLS and ESRF (Ferreira *et al.*, 2004). Kindly provided by Professor So Iwata, Imperial College, London.

Synchrotron structures deposited in the PDB *versus* all PDB deposited structures (from http://biosync.rcsb.org/BiosyncStat.html) as of December 2009, *i.e.* a majority of all determined macromolecular crystal structures are now synchrotron-radiation derived.

discovery [for an early description see Bugg *et al.* (1993), for an example of pharmaceutical company collaboration see the Industrial Macromolecular Crystallography Association (IMCA) Collaborative Access Team at APS in Chicago (http://www.imca.aps.anl.gov/) and for a recent European perspective see *e.g.* Maclean *et al.* (2006).]

8.1.8.6. Radiation damage

The successes of these sources in macromolecular crystallography have been spectacular, so much so that provision of such beamlines now accounts for ~40% of the APS and ESRF insertion-device sectors. Nevertheless, X-radiation damage has been a continuing concern not least as the 'cutting edge' of capability to study ever-smaller crystals and ever-larger unit cells at synchrotron-radiation sources has been improved and optimized. A notable development has been a series of International Workshops on X-ray Damage to Crystalline Biological Samples. Most of these workshops have resulted in special issues of the *Journal of Synchrotron Radiation* (Volume 9 part 6, Volume 12 part 3, Volume 14 part 1 and Volume 16 part 2). The latest of these has a mini-review by Garman & Nave (2009).

8.1.9. Concluding remarks

SR and crystallography are now intricately intertwined in their scientific futures and in facilities provision (see *e.g.* Helliwell, 1998; Dauter, 2006; Fig. 8.1.9.1). Jiang & Sweet (2004) have given a systematic analysis of the impact of SR on macromolecular crystallography capabilities.

The new XFELs have produced very novel possibilities for 3D structure determination not only of non-crystallizable proteins but also whole cells (Neutze *et al.*, 2000; Miao *et al.*, 2001; Sayre, 2008; Shapiro, 2008). Whilst these approaches have attracted controversy, they represent a bold new push of X-ray diffraction methods towards widening capabilities in important frontiers in structural biology and structural cellular biology.

Chapter 8.2. Laue crystallography: time-resolved studies

K. Moffat

8.2.1. Introduction

The term 'Laue diffraction' describes the process of X-ray scattering that occurs when a stationary crystal is illuminated by a polychromatic beam of X-rays. The process therefore differs from the now more conventional diffraction techniques in which a moving crystal is illuminated by a monochromatic beam of X-rays. Although Laue diffraction was widely used for structure analysis in the early days of crystallography by Pauling, Bragg, Wyckoff and others, by the 1930s it was superseded by arguably simpler and more readily quantifiable monochromatic techniques. With the advent of naturally polychromatic synchrotron sources in the 1970s, it was natural to (re-)examine the suitability of the Laue technique. The first synchrotron-based Laue experiments to be published appear to have been those of Wood *et al.* (1983) for a small inorganic crystal and of Moffat *et al.* (1984) for a macromolecular crystal; see also Helliwell (1984, 1985). These experimenters realized that the Laue technique afforded exposure times that were short even with respect to those obtainable with similar crystals at the same synchrotron source using conventional monochromatic techniques, and much shorter than those obtainable with laboratory X-ray sources. This advantage, along with the use of a stationary crystal, the large number of Laue spots evident in a single image and the clear distinction of the Laue spots from the underlying X-ray background, suggested that the Laue technique might be particularly applicable to time-resolved crystallography. In this form of crystallography, the total X-ray scattering from the crystal (both the Bragg scattering and the diffuse, non-Bragg scattering) varies with time as the position and/or extent of order of the atoms in the crystal changes in response to some structural perturbation.

It is one thing to propose that a venerable technique may be applicable to a new class of experiments; it is quite another to identify and overcome the complexities and disadvantages of that technique, and to demonstrate how experiments should be conducted and raw data accurately reduced to structure amplitudes. It took roughly 15 years and the efforts of many investigators before it could be stated that Laue crystallography is coming of age (Ren *et al.*, 1999).

The redevelopment of Laue diffraction has depended on three main advances: the use of very intense polychromatic synchrotron sources; the realization that the so-called energy-overlap or overlapping-orders problem in Laue diffraction was theoretically tractable, of limited extent and could be overcome experimentally; and the development of appropriate algorithms and suitable software to address the energy-overlap, spatial-overlap and wavelength-normalization problems. All are discussed below.

Since both Laue crystallography and its applications to time-resolved studies have recently been described at length, this article emphasizes only the key points and directs the reader to the primary and review literature for the details.

8.2.2. Principles of Laue diffraction

The principles of Laue diffraction have been reviewed by Amorós *et al.* (1975), Cruickshank *et al.* (1987, 1991), Helliwell *et al.* (1989), Cassetta *et al.* (1993), Moffat (1997), and Ren *et al.* (1999).

Assume that a stationary, perfect single crystal that diffracts to a resolution limit of $d^*_{\max}$ is illuminated by a polychromatic X-ray beam spanning the wavelength (energy) range from $\lambda_{\min}$ ($E_{\max}$) to $\lambda_{\max}$ ($E_{\min}$). All reciprocal-lattice points that lie between the Ewald spheres of radii $1/\lambda_{\min}$ and $1/\lambda_{\max}$, and within a radius $d^*_{\max}$ of the origin O where $d^*_{\max} = 1/d_{\min}$, the resolution limit of the crystal, are in a diffracting position for a particular wavelength λ, where $\lambda_{\min} \leq \lambda \leq \lambda_{\max}$ and will contribute to a spot on the Laue diffraction pattern (Fig. 8.2.2.1). All such points diffract simultaneously and throughout the exposure, in contrast to a monochromatic diffraction pattern in which each point diffracts sequentially and briefly as it traverses the Ewald sphere. A Laue pattern may alternatively be thought of as the superposition of a series of monochromatic still patterns, each arising from a different wavelength in the range from $\lambda_{\min}$ to $\lambda_{\max}$.

Each Laue spot arises from the mapping of a complete ray (a central line in reciprocal space, emanating from the origin) onto a point on the detector. In contrast, each spot in a monochromatic pattern arises from the mapping of a single reciprocal-lattice point onto a point on the detector. A ray may contain only a single reciprocal-lattice point *hkl* with spacing d^*, in which case the corresponding Laue spot arises from a single wavelength (energy) and structure amplitude, or it may contain several

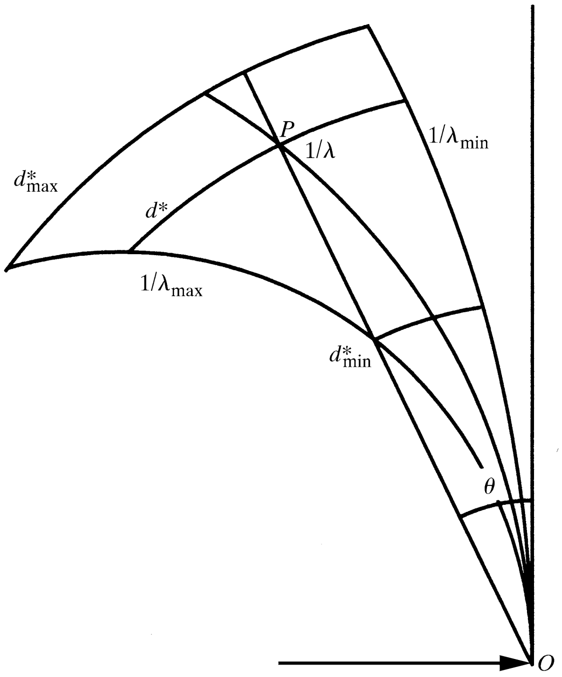

Figure 8.2.2.1
Laue diffraction geometry. The volume element dV stimulated in a Laue experiment lies between d^* and $d^* + dd^*$, between the Ewald spheres corresponding to λ and $\lambda + d\lambda$, and between φ and $\varphi + d\varphi$, where φ denotes rotation about the incident X-ray beam direction. The entire volume stimulated in a single Laue exposure lies between 0 and $d^*_{\max}$, between the Ewald spheres corresponding to $\lambda_{\min}$ and $\lambda_{\max}$, and between values of θ ranging from 0 to 2π.

reciprocal-lattice points, such as $hkl, 2h2k2l \ldots nhnknl \ldots$, in which case the Laue spot contains several wavelengths (energies) and structure amplitudes. In the former case, the Laue spot is said to be single, and in the latter, multiple. The existence of multiple Laue spots is known as the energy-overlap problem: one spot contains contributions from several energies. It seems to have been thought by Pauling, Bragg and others that, as the wavelength range and the resolution limit $d^*_{\rm max}$ of the crystal increased, more and more Laue spots would be multiple and the energy-overlap problem would dominate. Cruickshank *et al.* (1987) showed that this was not so. Even in the extreme case of infinite wavelength range, no more than 12.5% of all Laue spots would be multiple. The energy-overlap problem is evidently of restricted extent. However, the magnitude of the energy-overlap problem varies with resolution: reciprocal-lattice points at low resolution are more likely to be associated with multiple Laue spots than to be single (Cruickshank *et al.*, 1987).

The extraction of X-ray structure amplitudes from a single Laue spot requires the derivation and application of a wavelength-dependent correction factor known as the wavelength normalization curve or λ-curve. This curve and other known factors relate the experimentally measured raw intensities of each Laue spot to the square of the corresponding structure amplitude. The integrated intensity of a Laue spot is achieved automatically by integration over wavelength, rather than in a monochromatic spot by integration over angle as the crystal rotates. If, however, a Laue spot is multiple, its total intensity arises from the sum of the integrated intensities of each of its components, known also as harmonics or orders *nhnknl* of the inner point *hkl* where *h*, *k* and *l* are co-prime.

Laue spots lie on conic sections, each corresponding to a central zone [*uvw*] in reciprocal space. Prominent spots known as nodal spots or nodals lie at the intersection of well populated zones and correspond to rays whose inner point *hkl* is of low co-prime indices. All nodal spots are multiple and all are surrounded by clear areas devoid of spots.

The volume of reciprocal space stimulated in a Laue exposure, V_v, is given by

$$V_v = 0.24\, d^{*4}_{\rm max}(\lambda_{\rm max} - \lambda_{\rm min}),$$

and contains N_v reciprocal-lattice points where $N_v = V_v/V^*$ and V^* is the volume of the reciprocal unit cell (Moffat, 1997). N_v can be large, particularly for crystals that diffract to high resolution and thus have larger values of $d^*_{\rm max}$. Laue patterns may therefore contain numerous closely spaced spots and exhibit a spatial-overlap problem (Cruickshank *et al.*, 1991). The value of N_v is up to an order of magnitude greater than the typical number of spots on a monochromatic oscillation pattern from the same crystal. Since the overall goal of a diffraction experiment is to record all spots in the unique volume of reciprocal space with suitable accuracy and redundancy, a Laue data set may contain fewer images and more spots of higher redundancy than a monochromatic data set (Clifton *et al.*, 1991). This is particularly evident if the crystal is of high symmetry.

Kalman (1979) provided derivations of the integrated intensity of a single spot in the Laue case and in the monochromatic case. Moffat (1997) used these to show that the duration of a typical Laue exposure was between three and four orders of magnitude less than the corresponding monochromatic exposure. The physical reason for this significant Laue advantage lies in the fact that all Laue spots are in a diffracting position and contribute to the integrated intensity throughout the exposure. In contrast, monochromatic spots diffract only briefly as each sweeps through the narrow Ewald sphere [more strictly, through the volume between the closely spaced Ewald spheres corresponding to $1/\lambda$ and $1/(\lambda + d\lambda)$]. The details are modified slightly for mosaic crystals of finite dimensions subjected to an X-ray beam of finite cross section and angular crossfire (Ren *et al.*, 1999; Z. Ren, unpublished results).

Exposure times are governed not merely by the requirement to generate sufficient diffracted intensity in a spot – the signal – but also to minimize the background under the spot – the noise. The background under a Laue spot tends to be higher than under a monochromatic spot, since it arises from a larger volume of reciprocal space in the Laue case. This volume extends from $d^*_{\rm min}$ (where $d^*_{\rm min} = 2\sin\theta/\lambda_{\rm max}$ and θ is the Bragg angle for that Laue spot) through the Laue spot at d^* to either $d^*_{\rm max}$ or $2\sin\theta/\lambda_{\rm min}$, whichever is the smaller (Moffat *et al.*, 1989). Since both the signal and the noise in a Laue pattern are directly proportional to the exposure time, their ratio is independent of that parameter. The ratio does depend on the wavelength range $(\lambda_{\rm max} - \lambda_{\rm min})$. Decreasing the wavelength range both generates fewer spots and increases the signal-to-noise ratio for each remaining spot by diminishing the background under it. This is analogous to decreasing the oscillation range in a monochromatic exposure.

The choice of appropriate exposure time in the Laue case is complicated, but the central fact remains: both in theory and in practice, Laue exposures are very short with respect to monochromatic exposures (Moffat *et al.*, 1984; Helliwell, 1985; Moffat, 1997). Satisfactory Laue diffraction patterns have been routinely obtained with X-ray exposures of 100 to 150 ps, corresponding to the duration of a single X-ray pulse emitted by a single 15 mA bunch of electrons circulating in the European Synchrotron Radiation Facility (ESRF) (Bourgeois *et al.*, 1996).

The advantages and disadvantages of the Laue technique, compared to the better-established and more familiar monochromatic techniques, are presented in Table 8.2.2.1.

8.2.3. Practical considerations in the Laue technique

The experimental aspects of a Laue experiment – the source and optics, the shutters and other beamline components, detectors, analysis software, and the successful design of the Laue experiments themselves – have been presented by Helliwell *et al.* (1989), Ren & Moffat (1994, 1995*a*,*b*), Bourgeois *et al.* (1996), Ren *et al.* (1996), Clifton *et al.* (1997), Moffat (1997), Yang *et al.* (1998), and Ren *et al.* (1999). Certain key parameters are under the experimenter's control, such as the nature of the source (bending magnet, wiggler or undulator), the wavelength range incident on the crystal (as modified by components of the beamline such as a mirror and attenuators), the choice of detector (active area, number of pixels and the size of each, dependence of detector parameters on wavelength, inherent background, and the accuracy and speed of readout), the experimental data-collection strategy (exposure time or times, number of angular settings of the crystal to be employed and the angular interval between them) and the data-reduction strategy (properties of the algorithms employed and of the software analysis package). A successful Laue experiment demands consideration of these parameters jointly and in advance, as described in these references. The goal is accurate structure amplitudes, not just speedily obtained, beautiful diffraction images.

For example, an undulator source yields a spectrum in which the incident intensity varies sharply with wavelength. Such a source should only be employed if the software can model this

Table 8.2.2.1

Advantages and disadvantages of the Laue technique

This table is adapted from Moffat (1997). See also Ren *et al.* (1999).

Advantages
Shortest possible exposure time, well suited to rapid time-resolved studies that require high time resolution.
Insensitive to all temporal fluctuations in the beam incident on the crystal, whether arising from the source itself, the optical components of the beamline or the shutter train. (Sensitive only to unusual fluctuations of the shape of the incident spectrum with time.)
All spots in a local region of the detector have an identical profile; none are (geometrically) partial.
Requires a stationary crystal and relatively simple optical components, therefore images are easy to acquire.
A large volume of reciprocal space is surveyed per image, hence fewer images are necessary to survey the entire unique volume.
High redundancy of measurements readily obtained, particularly at high resolution.
Disadvantages
Energy overlaps must be deconvoluted into their components if complete data are to be obtained, particularly at low resolution.
Spatial overlaps are numerous, particularly for mosaic crystals, and must be resolved.
Completeness at low resolution may be low, which would lead to significant series-termination errors in Fourier maps.
The rate of heating owing to X-ray absorption can be very high.
The wider the wavelength range, the higher the background under each spot; a trade-off is unavoidable between coverage of reciprocal space and accuracy of intensity measurements.
Spot shape is quite sensitive to crystal disorder.
More complicated wavelength-dependent corrections must be derived and applied to spot intensities to yield structure amplitudes.

variation suitably in the derivation of the wavelength normalization curve. This is indeed so (at least for the *LaueView* software package) even in the most extreme case, that of the so-called single-line undulator source in which $\lambda_{\max}$ and $\lambda_{\min}$ may differ by only 10%, say by 0.1 Å at 1.0 Å (V. Šrajer *et al.* and D. Bourgeois *et al.*, in preparation).

As a second example, a Laue diffraction pattern is particularly sensitive to crystal disorder, which leads to substantial 'streaking' of the Laue spots that is predominantly radial in direction in each diffraction image and may be dependent both on direction in reciprocal space (anisotropic disorder) and on time (if, in a time-resolved experiment, disorder is induced by the process of reaction initiation or by structural evolution as the reaction proceeds). The software therefore has to be able to model accurately elongated closely spaced or partially overlapping spots, whose profile varies markedly with position on each detector image and with time (Ren & Moffat, 1995*a*). If the software has difficulty with this task, then either a more ordered crystal must be selected, thus diminishing the size of each spot and the extent of spatial overlaps, or a narrower wavelength range must be used, thus reducing the total number of spots per image and their average spatial density (Cruickshank *et al.*, 1991); or the crystal-to-detector distance must be increased, thus increasing the average spot-to-spot distance and potentially increasing the signal-to-noise ratio. There are, however, trade-offs. More ordered crystals may not be readily available, a narrower wavelength range means that more images are required for a complete data set and the detector must continue to intercept all of the high-angle diffraction data (which consist largely of single spots stimulated by longer wavelengths).

As a third example, consider radiation damage. This can be purely thermal, arising from heating due to X-ray absorption. The rate of temperature rise may easily reach several hundred kelvin per second from a focused pink bending-magnet beam at second-generation sources such as the National Synchrotron Light Source (NSLS) (Chen, 1994; Moffat, 1997) or several thousand kelvin per second from a focused wiggler source at third-generation sources such as the ESRF. Fast shutters are required to provide an individual exposure of one millisecond or less in the latter case, and hence to limit the temperature rise to a readily survivable value of several kelvin (Bourgeois *et al.*, 1996; Moffat, 1997). Primary radiation damage (arising directly from X-ray absorption and hence from energy deposition) cannot be eliminated, but it may be modified by selection of the wavelength range and by lowering $\lambda_{\max}$. Secondary radiation damage, arising from the chemical and structural damage generated by highly reactive, rapidly diffusing free radicals, hydrated electrons and other chemical species, can be greatly minimized by the use of very short exposures which allow little time for damaging reactions to occur, and by working at cryogenic temperatures where diffusion is greatly reduced (see *e.g.* Garman & Schneider, 1997). However, the last strategy may not be an option in a time-resolved Laue experiment, where the desired structural transitions may be literally frozen out at cryogenic temperatures.

Extraction of structure amplitudes from a Laue image or data set proceeds through five stages, reviewed in detail by Clifton *et al.* (1997) and Ren *et al.* (1999), and outlined in Fig. 8.2.3.1. First comes the purely geometrical process of indexing, in which each spot is associated with the appropriate *hkl* value and the unit-cell parameters, crystal orientation matrix, $\lambda_{\min}$, geometric parameters of the detector and X-ray camera, $\lambda_{\max}$ and $d^*_{\max}$ are refined, also yielding λ, the wavelength stimulating that spot. In the second stage, each spot is integrated using appropriate profile-fitting algorithms. Thirdly, the wavelength normalization curve is derived, usually by comparison of the recorded intensities of the same (single) spots or symmetry-related spots at several crystal orientations, applied to each image, and the images in each data set scaled together. In the fourth stage, the intensities of spots identified in the first stage as multiple are resolved (or deconvoluted) into the intensity of each individual component or harmonic. The total intensity of a multiple Laue spot is the weighted sum of the intensities of each component, and the weights are known from the wavelength assigned to each component (Stage 1) and the wavelength normalization curve (Stage 3). In the fifth stage, the single and multiple data are merged and reduced to structure amplitudes. Ren *et al.* (1999) have emphasized that, in contrast to the simplified description presented in Section 8.2.2, the effective wavelength range $\lambda_{\max} - \lambda_{\min}$ depends on resolution, and each Laue spot is stimulated by a range of wavelengths which can be quite large at low resolution. Although typical Laue software packages such as the *Daresbury Laue Software Suite* (Helliwell *et al.*, 1989; Campbell, 1995), *LEAP* (Wakatsuki, 1993) and *LaueView* (Ren & Moffat, 1995*a*,*b*) are largely automated, a surprising degree of manual intervention may still be required in the first (indexing) stage, and in later stages where the order of parameter refine-

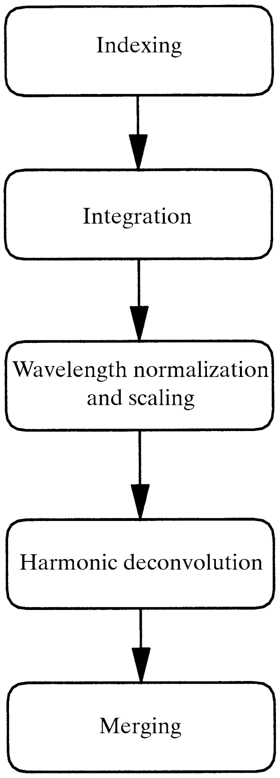

Figure 8.2.3.1
Flow chart of typical Laue data processing.

ment and various rejection criteria may be adjusted by the user. The overall result is that carefully conducted Laue experiments yield structure amplitudes that equal those from monochromatic data in quality (Ren *et al.*, 1999).

8.2.4. The time-resolved experiment

The principles and applications of time-resolved macromolecular crystallography have been widely reviewed (Moffat, 1989; Cruickshank *et al.*, 1992; Hajdu & Johnson, 1993; Helliwell & Rentzepis, 1997; Moffat, 1998; Ren *et al.*, 1999). This article therefore concentrates on the crystallographic aspects.

The essence of a perfect time-resolved crystallographic experiment is that a structural reaction is initiated in all the molecules in the crystal, rapidly, uniformly and in a non-damaging manner. The molecules, far from thermodynamic equilibrium immediately after the completion of the initiation process, relax through a series of structural transitions back to equilibrium. The course of the structural transitions is monitored through the time-dependence of the X-ray scattering. The structure amplitudes (and indeed the phases) associated with each Bragg peak *hkl* become time-dependent and may be denoted $|F(hkl, t)|$. The Fourier transform of the structure factors yields the time-dependent space-average structure of the molecules in the crystal. If all molecules behave independently of one another in the crystal, as they do in dilute solution, then the overall time dependence arises from the time dependence of the fractional populations of each time-independent structural state. That is, the crystal exhibits time-dependent substitutional disorder. (Lest this seem an unfamiliar concept, recall that a multi-site, partially occupied, heavy-atom derivative also exhibits substitutional disorder: the contents of each unit cell differ slightly, depending on whether a particular heavy-atom site is occupied in that unit cell or not. Such disorder fortunately does not invalidate the use of that derivative. The analysis proceeds as though a particular site were, say, 70% occupied in every unit cell of the crystal, although in reality that site is 100% occupied in 70% of the unit cells. In this example, the substitutional disorder is time-independent.) The crystal is thus imperfect: substitutional disorder breaks the translational symmetry. It follows that there must also be time-dependent non-Bragg scattering; but all studies to date have focused on the Bragg scattering.

The above describes a perfect experiment but, as might be expected, reality is different. Initiation techniques such as absorption of light from a laser pulse (Schlichting & Goody, 1997) unavoidably deposit energy in the crystal and give rise to a temperature jump and transient, reversible crystal disorder, evident as spot streaking. The magnitude of this temperature jump is proportional to the number of photons absorbed, which in turn is related to the concentration of photoactive species, the quantum yield for photoactivation and the fraction of molecules stimulated (Moffat, 1995, 1998). The necessity for limiting the magnitude of this temperature jump to retain crystallinity means that it is difficult to initiate the reaction in all molecules in the crystal. For example, photodissociation of carbon monoxide from carbonmonoxymyoglobin crystals was achieved in roughly 40% of the molecules (Šrajer *et al.*, 1996), and entry into the photocycle of photoactive yellow protein in roughly 20% of the molecules (Perman *et al.*, 1998). The magnitude of the time-dependent change in structure-factor amplitudes, given by

$$\Delta F(hkl, t) = |F(hkl, t)| - |F(hkl, 0)|,$$

is proportional to the fraction of molecules photoactivated and is therefore substantially diminished.

The main crystallographic challenge thus becomes the accurate determination of small values of $\Delta F(hkl, t)$ in the face of both random errors (arising from, for example, the small numbers of diffracted photons into the reflection *hkl* from a brief X-ray pulse) and systematic errors (arising from, for example, inaccurate determination of the Laue wavelength normalization curve, crystal-to-crystal scaling errors, inadequately corrected absorption effects, or time-dependent spot profiles). Precision is enhanced by acquiring highly redundant Laue data (mean redundancies typically between 5 and 15), which also afford an excellent measure of the variance of the structure amplitudes, and accuracy is enhanced by interleaving measurements of $|F(hkl, t)|$ with those of $|F(hkl, 0)|$ on the same crystal, at nearly the same time. Indeed, 'two-spot' Laue patterns may be acquired by recording both the $|F(hkl, t)|$ and $|F(hkl, 0)|$ diffraction patterns, slightly displaced with respect to each other, on the same detector [image plate or charge-coupled device (CCD)] prior to readout and quantification (Ren *et al.*, 1996). However, this doubles the background and halves the signal-to-noise ratio.

The values of $\Delta F(hkl, t)$ span a four-dimensional space. What is the best way to scan this four-dimensional space, having regard for the need to minimize errors? Interleaving measurements of $|F(hkl, t)|$ and $|F(hkl, 0)|$ has been achieved by fixing the delay time t between reaction initiation (the pump, laser pulse) and X-ray data acquisition (the probe, X-ray pulse), and surveying all values of *hkl* through progressive reorientation of the crystal between Laue images until all the unique volume of reciprocal space is surveyed with adequate redundancy and completeness (Šrajer *et al.*, 1996; Perman *et al.*, 1998; Ren *et al.*, 1999). The value of t is then altered and data acquisition repeated for all suitable values of t. That is, t is the slow variable. The difficulty with this approach is that a single crystal may yield only one or two data sets, corresponding to one or two values of t, before radiation damage (predominantly laser-induced rather than X-ray-induced) compels replacement of the crystal. The entire reaction time course over all values of t must therefore be pieced together from measurements on many crystals, a process which is prone to inter-crystal scaling errors. A second experimental approach to scanning this four-dimensional data space is therefore to fix the crystal orientation, obtain values of $|F(hkl, t)|$ and $|F(hkl, 0)|$ for all suitable values of t, reorient the crystal, recollect these same values of t, then replace the crystal and repeat until all the unique volume of reciprocal space is surveyed. That is, *hkl* are the slow variables (B. Perman, S. Anderson & Z. Ren, unpublished results). This approach yields a more accurate time course, but (for a single crystal) from a subset of reflections only. In practice, of the order of 100 time points t may be collected.

Table 8.2.5.1
Time-resolved Laue diffraction experiments

This table is adapted from Table 2 of Ren *et al.* (1999), in which citations of the original experiments are provided.

Protein	Time resolution	Experiment
Hen lysozyme	64 ms	Temperature jump test
Glycogen phosphorylase	1 s	Bound maltoheptose
Hen lysozyme	1 s	Radiation damage test
Glycogen phosphorylase	100 ms	Use of caged phosphate
Ras oncogene product	1 s	GTP complex
γ-Chymotrypsin	5 s	Photolysis of cinnamate/pyrone
Trypsin	800 ms	Ordered hydrolytic water
Cytochrome *c* peroxidase	1 s	Redox active compound I
Hen lysozyme	10 ms	Temperature jump
Isocitrate dehydrogenase	50 ms	ES complex and intermediate
Isocitrate dehydrogenase	10 ms	Product complex
Photoactive yellow protein	10 ms	*p*B-like intermediate
Photoactive yellow protein	10 ns	*p*R-like intermediate
CO-myoglobin	10 ns	Photolyzed CO species at 290 K
CO-myoglobin	8 ms	Photolyzed CO species at 20–40 K
Hydroxymethylbilane synthase	1.5 ms	Mutant enzyme–cofactor complex

The first approach permits Fourier or difference Fourier maps to be calculated using data from a single crystal at one or a small number of time delays t. The second approach requires data from many crystals to be acquired before such maps can be calculated. This complicates the issue of which is the better approach. Preliminary results (V. Šrajer & B. Perman, unpublished results) suggest that genuine features may be reliably distinguished in real space by examination of Fourier and difference Fourier maps, but genuine trends in reciprocal space are much harder to discern.

How many features can be distinguished as genuine in real space, in, for example, a difference Fourier map? We presently employ three criteria. First, the feature must be 'significant' in crystallographic terms. That is, its peak height must exceed (say) 4σ to 5σ, where σ is the r.m.s. value of the difference electron density $\Delta\rho$ across the asymmetric unit, in a difference Fourier map. Second, the feature must be chemically plausible, *e.g.* located on or near critical groups in the active site. Third, the feature must persist over several time points. No genuine feature is likely to vary faster than exponentially in time (though slower variation is possible), but noise features tend to come and go, varying rapidly with time. The third criterion, which in effect is applying a low-pass temporal filter to the data, or 'time-smoothing', is only applicable if several time points are available per decade of time t. It is to ensure that this powerful criterion can be applied in an unbiased manner that the time points t at which data are acquired are uniformly and closely spaced in log t.

Suppose that complete and accurate values of $|F(hkl, t)|$ are available to high resolution and at numerous values of t. How can these time-dependent data be further analysed to yield information on the reaction mechanism and the time-dependent structures of intermediates? Each candidate chemical-kinetic mechanism implies a different time-dependent mixture of structural states at all times t. For each mechanism, a set of trial time-dependent intermediate structures can be calculated from the time-dependent data (Perman, 1999). One then asks: Is each trial intermediate structure an authentic, single, stereochemically plausible, refinable protein structure? If so, the mechanism is supported, but if not, the mechanism is rejected. This process, of seeking to extract time-independent structures from time-dependent data, is closely related to the better-understood process of extracting time-independent difference spectra from time-dependent optical absorption data *via*, for example, singular value decomposition or principal component analysis. The latter, optical analysis, proceeds in two dimensions, $\mathrm{OD}(\lambda, t)$; the former, crystallographic analysis, must proceed in four dimensions, either $\rho(xyz, t)$ or $|F(hkl, t)|$.

It will be appreciated that the acquisition of fast, time-resolved data is greatly hindered by the lack of a time-slicing area detector. This lack is even more evident when the structural reaction is irreversible as, for example, in the photoactivation of caged GTP to GTP (Schlichting *et al.*, 1990). In such cases, the reactants must be replenished prior to each reaction initiation, which makes the acquisition of time-resolved data particularly tedious. The present generation of CCD detectors have an inter-frame time delay in the millisecond (or just sub-millisecond) time range. Pixel array detectors under development may permit the acquisition of sequential images with a time delay in the microsecond range. The desirable nanosecond or even picosecond time range seems inaccessible for area detectors (but not for point detectors such as streak cameras). A new approach may be needed, such as the use of chirped hard X-ray pulses which, in combination with Laue diffraction, map X-ray energy into both reciprocal space (*hkl*) and time (K. Moffat, in preparation).

8.2.5. Conclusions

Only a small number of biochemical systems have been subjected to time-resolved crystallographic analysis (Table 8.2.5.1; Ren *et al.*, 1999). The experiments are technically demanding, require careful planning in the execution, in data analysis and in data interpretation, and strategies for the evaluation of mechanism are still being developed. However, road maps exist for several successful classes of experiments (see *e.g.* Stoddard *et al.*, 1998; Moffat, 1998; Ren *et al.*, 1999) and new biological systems to which such analyses may be readily applied are being developed. In a world of structural genomics where structures themselves are ten-a-penny, a structure-based understanding of mechanism at the chemical level is still rare. The contributions of crystallography to functional – not merely structural – genomics may be large indeed.

This work was supported by the NIH. I thank Zhong Ren for comments on the manuscript.

PART 9. X-RAY DATA COLLECTION

Chapter 9.1. Principles of monochromatic data collection

Z. Dauter and K. S. Wilson

9.1.1. Introduction

X-ray data collection is the central experiment in a crystal structure analysis. For small-molecule structures, the availability of intensity data to atomic, usually around 0.8 Å, resolution means that the phase problem can be solved directly and the atomic positions refined with a full anisotropic model. This results in a truly automatic structure solution for most small molecules.

Macromolecular crystals pose much greater problems with regard to data collection. The first arise from the size of the unit cell, resulting in lower average intensities of individual reflections coupled with a much greater number of reflections (Table 9.1.1.1). Secondly, the crystals usually contain considerable proportions of disordered aqueous solvent, giving further reduction in intensity at high resolution and, in the majority of cases, restricting the resolution to be much less than atomic. Thirdly, the crystals are sensitive to radiation damage (see Section 9.1.12). Such problems have severe implications for all subsequent steps in a structure analysis. Solution of the phase problem is generally not possible through direct methods, except for a small number of exceptionally well diffracting proteins. The refined models require the imposition of stereochemical constraints or restraints to maintain an acceptable geometry.

At modern synchrotron beamlines, cryogenic cooling and high-efficiency two-dimensional (2D) detectors have made data collection technically easier, but it remains a fundamental scientific procedure underpinning the whole structural analysis. Therefore, it is essential to take the greatest care over this key step. The aim of this chapter is to indicate procedures for optimizing data acquisition. Overviews on several issues related to this topic have been published (Carter & Sweet, 1997; Evans & Walsh, 2005; Dauter, 2005).

9.1.2. The components of a monochromatic X-ray experiment

To collect X-ray data from single crystals, the following elements are required:

(1) a source of X-rays;
(2) optical elements to focus the X-rays onto the sample;
(3) a monochromator to select a single wavelength;
(4) a collimator to produce a beam of defined dimension;
(5) a shutter to limit the exposure of the sample to X-rays;
(6) a goniostat with associated sample holder to allow rotation of the crystal;
(7) the crystalline sample itself;
(8) a cryogenic cooling device for vitrified crystals;
(9) an efficient, generally 2D, detector system;
(10) software to control the experiment and store and display the X-ray images;
(11) data-processing software to extract intensities and associated standard uncertainties for the Bragg reflections in the images.

On a number of beamlines, automated procedures have been implemented for sample changing, automatic crystal centring, evaluating the diffraction and proposing a strategy for data collection. These allow rapid and more effective selection of the best sample and optimal parameters.

Many of these are discussed elsewhere in this volume. This chapter aims to provide guidance in those areas where choices are to be made by the experimenter and is concerned with the interrelations between parameters and how they conspire for or against different strategies of data collection.

9.1.3. Data completeness

The advantage of diffraction methods over spectroscopy is that they provide a full 3D view of the object. Diffraction methods are theoretically limited by the wavelength of the radiation used, but, in practice, every diffraction experiment is further limited by the aperture and quality of the lens. In the X-ray experiment, the aperture corresponds to the resolution limit and the quality of the 'lens' to the completeness and accuracy of the measured Bragg reflection intensities.

In this context, completeness has two components, the first of which is geometric and hence quantitative. It is necessary to rotate the crystal so that all unique reciprocal-lattice points pass through the Ewald sphere and the associated intensities are recorded on the detector. Ideally, the intensities of 100% of the unique Bragg reflections should be measured. The second component is qualitative and statistical: for each *hkl*, the intensity, I_{hkl}, should be significant, with its accuracy correctly estimated in the form of an associated standard uncertainty, $\sigma(I)$. The data should be significant in terms of the $I/\sigma(I)$ ratio throughout the resolution range. This point will be returned to below, but it is especially important that the data at low resolution are complete and not overloaded on the detector, and that there is not a significant fraction of essentially zero-level intensities in the higher-resolution shells.

9.1.4. X-ray sources

There are two principal sources of X-rays appropriate for macromolecular data collection: rotating anodes and synchrotron storage rings. These are not discussed in detail here as they are described in Chapters 6.1 and 8.1.

Table 9.1.1.1
Size of the unit cell and number of reflections

Compound	Unit cell Edge (Å)	Volume (Å^3)	Reflections	Average intensity
Small organic	10	1000	2000	1
Supramolecule	30	25000	30000	1/25000
Protein	100	1000000	100000	1/1000000
Virus	400	100000000	1000000	1/100000000

9.1.4.1. *Conventional sources*

Rotating anodes were initially developed for biological scattering experiments on muscle samples and have the advantage of higher intensity compared with sealed-tube generators. They usually have a copper target providing radiation at a fixed wavelength of 1.542 Å. Alternative targets, such as silver or molybdenum, provide lower intensities at short wavelengths, but have not found general applications to macromolecules. It is also possible to use a chromium target, giving a longer wavelength of 2.29 Å. Historically, rotating anodes were first used with nickel filters to give monochromatic Cu *Kα* radiation. Current systems are equipped with either graphite monochromators, a focusing mirror or multilayer optics. The latter provide substantially enhanced intensity. Rotating anodes remain the source of choice in most structural biology laboratories. An important choice for the user is in the selection of optimal collimator aperture: this should roughly match the crystal sample dimensions. For large crystals, especially if the cell dimensions are also large, it may be preferable to use collimator settings smaller than the crystal in order to resolve the diffraction spots on the detector. Considerable progress has been made in the technologies for rotating anodes in recent years, as well as in the development of high-intensity sealed-tube sources for home laboratories (Bloomer & Arndt, 1999).

9.1.4.2. *Synchrotron storage rings*

The radiation intensity available from rotating anodes is limited by the heat load per unit area on the target. In the early 1970s, it was realized that synchrotron storage rings produced X-radiation in the necessary spectral range for studies in structural molecular biology (Rosenbaum *et al.*, 1971), and the last four decades have seen great advances in their application to macromolecular crystallography (Helliwell, 2004; Hendrickson, 2000). Synchrotron radiation (SR) is now used for the great majority of newly determined protein-crystal structures.

The general advantages of SR are:

(1) High intensity: third-generation sources provide more than 1000 times the intensity of a conventional source.
(2) A highly parallel beam allowing the resolution of closely spaced spots from large unit cells.
(3) Short wavelengths, less than 1 Å, essentially eliminating the problems of correcting for absorption.
(4) Tunability of the wavelength, allowing its optimization for single- or multiple-wavelength applications; this is simply not possible with a conventional source.
(5) The ability to use a white, non-monochromated beam, the so-called Laue technique discussed in Chapter 8.2.

SR beamlines take a number of forms. The source may be a bending magnet or an insertion device, such as a wiggler or an undulator. The properties of different beamlines thus vary considerably and it is vital to choose an appropriate beamline for any particular application. The beamline capabilities are, of course, affected by the detector as well as the source itself. As far as the user is concerned, the primary questions regard the intensity, the size of the focal spot, the wavelength tunability and the detector system.

The present consensus for new synchrotron beamlines for macromolecular crystallography is that they should be on sources with an energy of at least 3 GeV and should receive radiation from tunable undulators. Together, these provide high and tunable intensity over the range required for most crystallographic experiments, including multiwavelength anomalous dispersion (MAD). The impact of free-electron lasers, which are currently under construction at a number of sites, is not yet possible to assess.

Present beamlines produce radiation of extremely high quality for macromolecular data collection. At third-generation sources complete data sets can be collected from cryogenically vitrified single crystals in minutes.

9.1.5. Goniostat geometry

9.1.5.1. *Overview*

The diffraction condition for a particular reflection is fulfilled when the corresponding reciprocal-lattice point lies on the surface of the Ewald sphere. If a stationary crystal is irradiated by the X-ray beam, only a few reflections will lie in the diffracting position. To record intensities of a larger number of reflections, either the size of the Ewald sphere or the crystal orientation has to be changed. The first option, with the use of non-monochromatic, or 'white', radiation, is the basis of the Laue method (Chapter 8.2). If the radiation is monochromatic, *i.e.* single-wavelength, the crystal has to be rotated during exposure to bring successive reflections into the diffraction condition.

9.1.5.2. *The screenless rotation method and 2D detectors*

In the early days of protein crystallography, a number of geometries were used for X-ray cameras, notably the Weissenberg and precession methods. In addition, single-counter diffractometers were used with four-circle goniostats. However, in practice only the screenless rotation geometry (Arndt & Wonacott, 1977) survives today. This requires a 2D detector, which was initially in the form of photographic film. It is of significance that typical film sizes were of the order of 10 × 10 cm with up to 2000 × 2000 scanned pixels; a similar effective area has proved effective for image plates and charge-coupled devices (CCDs).

However, automation of protein-data collection needed efficient 2D detectors (Part 7). The first were multiwire proportional counters, which found widespread use in the early 1980s (Hamlin, 1985). These finally proved to be limited by a combination of spatial resolution and dead time of the read-out. A major advance occurred in the late 1980s with the widespread introduction of imaging plates (Amemiya, 1995), scanned on-line both at synchrotron beamlines and on laboratory rotating-anode sources. This represented a revolution in macromolecular data collection, making it technically straightforward to save full 2D images with sufficient positional resolution and dynamic range to computer disk automatically. The limiting factor of the imaging plate proved to be the slow read-out time of the order of several seconds to minutes. At high-intensity sources in particular, *e.g.* third-generation SR sites, exposure times per image can fall to one second or less, and with an imaging plate the bulk of the time is spent reading the detector image rather than collecting data. Typical data-collection times with imaging plates remained of the order of several hours, even with the use of SR. This is a much smaller problem with rotating-anode sources, where exposure times dominate the duty cycle.

For high-intensity SR sites, the detector of choice is the CCD (Gruner & Ealick, 1995). The spatial resolution is comparable with that of imaging plates, but the read-out time can be as low as one to two seconds. This means that complete data can be

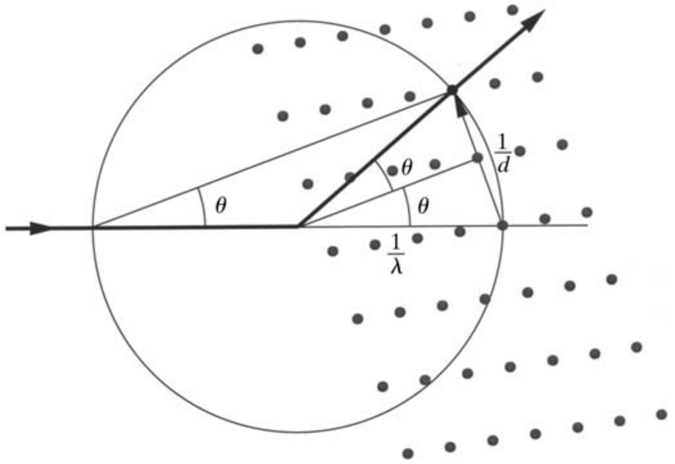

Figure 9.1.6.1
The Ewald-sphere construction. A reciprocal-lattice point lies on the surface of the sphere if the following trigonometric condition is fulfilled: $1/2d = (1/\lambda)\sin\theta$. After a simple rearrangement, it takes the form of Bragg's law: $\lambda = 2d\sin\theta$. Therefore, when a reciprocal-lattice point with indices *hkl* lies on the surface of the Ewald sphere, the interference condition for that particular reflection is fulfilled and it gives rise to a diffracted beam directed along the line joining the centre of the sphere to the reciprocal-lattice point on the surface.

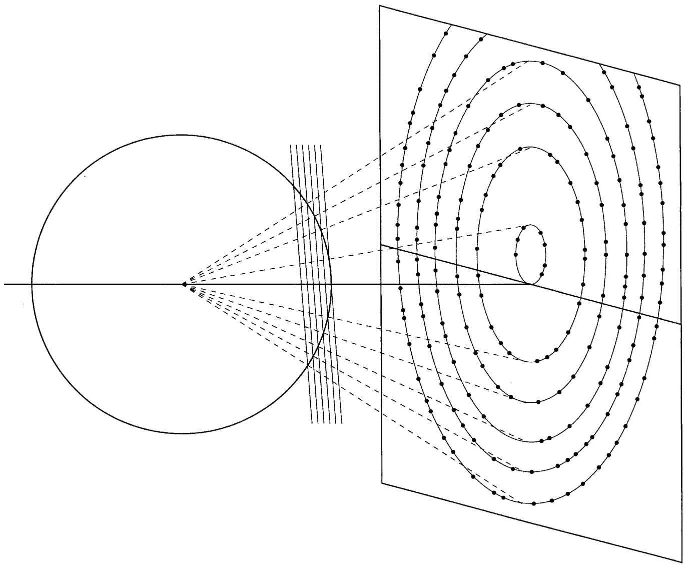

Figure 9.1.6.2
The plane of reflections in the reciprocal sphere that is approximately perpendicular to the X-ray beam gives rise to an ellipse of reflections on the detector.

recorded in minutes rather than hours and has transformed approaches to data collection.

While the CCD has revolutionized data-collection times, further advances are expected from the use of solid-state pixel detectors. Such detectors record individual X-ray quanta and have essentially zero read-out time. The most advanced of these, the PILATUS 1M device, is a hybrid pixel array detector (Broennimann *et al.*, 2006; Hülsen *et al.*, 2006), first installed at the Swiss Light Source.

Almost all current 2D detectors are used in conjunction with a goniostat, providing rotation of the crystal about a single axis during exposure. Indeed, the majority of instruments have only a single rotation axis. The remainder are based on the kappa (ω, κ, φ) cradle to select different initial orientations of the sample in the beam; the sample is nevertheless subsequently rotated about a single axis for data collection.

9.1.6. Basis of the rotation method

9.1.6.1. Rotation geometry

The physical process of diffraction from a crystal involves the interference of X-rays scattered from the electron clouds around the atomic centres. The ordered repetition of atomic positions in all unit cells leads to discrete peaks in the diffraction pattern. The geometry of this process can alternatively be described as resulting from the reflection of X-rays from a set of hypothetical planes in the crystal. This is explained by the Ewald construction (Fig. 9.1.6.1), which provides a visualization of Bragg's law. Monochromatic radiation is represented by a sphere of radius $1/\lambda$, and the crystal by a reciprocal lattice. The lattice consists of points lying at the end of vectors normal to reflecting planes, with a length inversely proportional to the interplanar spacing, $1/d$. In the rotation method, the crystal is rotated about a single axis, with the rotation angle defined as φ. A seminal work, giving an excellent background to this field by a number of contributors, was edited by Arndt & Wonacott (1977). A more recent review of the method is provided by Dauter (2005).

9.1.6.2. Diffraction pattern at a single orientation: the 'still' image

For a stationary crystal in any particular orientation (a so-called 'still' exposure), only a fraction of the total number of Bragg reflections will satisfy the diffracting condition. The number of reflections will be very limited for a small-molecule crystal, possibly zero in some orientations. Macromolecules have large unit cells, of the order of 100 Å, compared with the wavelength of the radiation, which is about 1.0 Å. In geometric terms, the reciprocal space is densely populated with points in relation to the size of the Ewald sphere. Thus, more reflections diffract simultaneously but at different angles, since many reciprocal-lattice points (reflections) lie simultaneously on the surface of the Ewald sphere in any crystal orientation. This is the great advantage of 2D detectors for large cell dimensions.

The real crystal is a regular and ordered array of unit cells. This means that reciprocal space is made up of a set of points organized in regular planes. For a still exposure, any particular plane of points in the reciprocal lattice intersects the surface of the Ewald sphere in the form of a circle. The corresponding diffracted rays, originating from the centre of the Ewald sphere, form a cone that intersects the sphere on the circle formed by the set of points. In most experiments, the detector is placed perpendicular to the direct beam and the cone of diffracted rays forms an ellipse of spots on its surface (Fig. 9.1.6.2). If a major axis of the crystal lies nearly parallel to the beam, then the ellipses will approximate a set of circles around the centre of the detector. All reflections within each circle will have one index in common, corresponding to the unit-cell axis lying along the beam. For non-centred unit cells, this index will increase by one in successive circles. The gaps between the circles depend on the spacing between the members of the set of reciprocal-lattice planes and are inversely proportional to the real cell dimension related to these planes.

Still exposures were used extensively in the early applications of the rotation method for estimation of crystal alignment. The geometric location of the spots with respect to the origin allows accurate determination of the unit-cell parameters and the crystal orientation. This approach has been superseded in modern

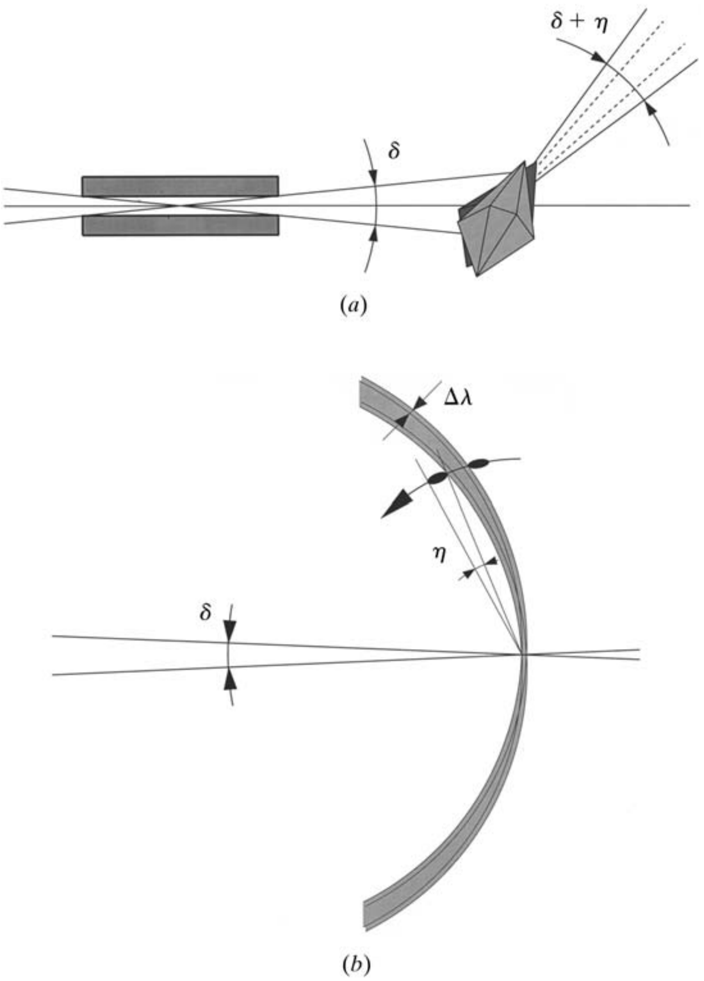

Figure 9.1.6.3
Schematic representation of beam divergence (δ) and crystal mosaicity (η). (*a*) In direct space, (*b*) in reciprocal space, where the additional thickness of the Ewald sphere results from the finite wavelength bandpass, $\delta\lambda/\lambda$.

software packages by autoindexing algorithms using real rotation images.

9.1.6.3. Rocking curve: crystal mosaicity and beam divergence

The Ewald-sphere construction assumes an ideal source with a totally parallel X-ray beam and an ideal crystal with all unit cells having identical relative orientation, resulting in infinitely sharp Bragg reflections. These assumptions lead to a sphere of radius $1/\lambda$ attached rigidly to the beam and with the crystal in a particular orientation as a reciprocal lattice consisting of mathematical points. A real experiment deviates from this in three respects. Firstly, the incident beam is not strictly parallel. On a conventional rotating-anode source the beam can only be focused and collimated to be parallel within a small angle, with a divergence of about 0.2° (with mirror optics) and 0.4° (with a monochromator). On SR sources, a much smaller beam divergence can be achieved, and, indeed, beamlines on third-generation SR sources approach the ideal ever more closely. The horizontal and vertical beam divergence may differ, and this must be taken into account. The Ewald sphere now has two limiting orientations which result in a nonzero active width. Secondly, the X-radiation is only monochromatic within a defined wavelength bandpass, $\delta\lambda/\lambda$, of the order 0.0002–0.001 at synchrotron beamlines, but considerably more for laboratory sources. The wavelength bandpass, in effect, thickens the surface of the Ewald sphere. Thirdly, real crystals are made up of small mosaic blocks imperfectly oriented relative to one another, increasing the total rocking curve. At room temperature, protein crystals often show a mosaic spread less than 0.05°, but for some samples this may be much larger. However, vitrification of crystals in many cases leads to substantial increase of mosaicity to sometimes more than 1°. In the reciprocal lattice, the effect of this is to give a finite dimension to each of the lattice points.

These effects are schematically illustrated in Fig. 9.1.6.3. The combined result is that the diffraction of a particular reflection is spread over a range of crystal rotation.

9.1.6.4. Rotation images and lunes

Using monochromatic radiation, in order to measure the remaining reflections that do not lie on the surface of the sphere, the crystal must be rotated to bring the reflections into the diffracting condition. If the crystal is rotated about a single axis during sequential exposures, this is known as the rotation method. The rotation axis is, in practice, chosen to be perpendicular to the beam to preserve the symmetry between the two halves of the complete pattern. This is the most commonly applied method of data collection for macromolecular crystals (Arndt & Wonacott, 1977).

If the crystal is rotated during exposure, the ellipses observed on a still image change their position on the detector. In effect, all reflections diffracting during one exposure will be contained within lunes formed between the two limiting positions of each ellipse at the start and end of the given rotation. The width of the lunes in the direction of the crystal rotation, perpendicular to the rotation axis, is proportional to the rotation range per exposure. In contrast, along the rotation axis the width of the lunes is very small, since the intersection of the reciprocal-lattice plane with the Ewald sphere does not change significantly. For crystals of small molecules, the lunes are not pronounced, owing to the sparse population of reciprocal space, but for crystals with large cell dimensions, the lunes are densely populated by diffraction spots and often exhibit clear and well pronounced edges. At high resolution, the mapping of the reciprocal lattice within each lune is distorted, and rows of reflections form hyperbolas. At low diffraction angles, where the surface of the Ewald sphere is approximately flat, this distortion is minimal, and the lunes look like fragments of precession photographs.

9.1.6.5. Partially and fully recorded reflections

The rotation method gives rise to lunes of data between the ellipses that relate to the start and the end of the rotation range used for the exposure. The data are complete if the Ewald sphere has been crossed by all reflections in the asymmetric part of the reciprocal lattice, which means that the crystal has to be rotated in total by a substantial angle. However, it is impossible to record all the data in a single exposure with such a wide rotation, owing to overlapping of the diffraction spots.

In practical applications to macromolecules, the total rotation is divided into a series of narrow individual rotations of width $\Delta\varphi$. In each of these, the crystal is exposed for a specified time or X-ray dose per angular unit. Each reflection diffracts over a defined crystal rotation and hence time interval, owing to the finite value of the rocking curve or angular spread, here referred to as ξ, the combined effect of beam divergence (δ) and crystal mosaicity (η). Provided ξ is less than $\Delta\varphi$, some reflections will start and finish crossing the Ewald sphere and hence diffract within one exposure. Their full intensity will be recorded on a

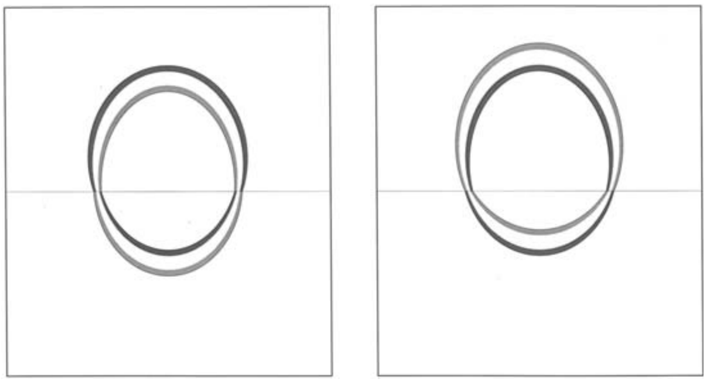

Figure 9.1.6.4
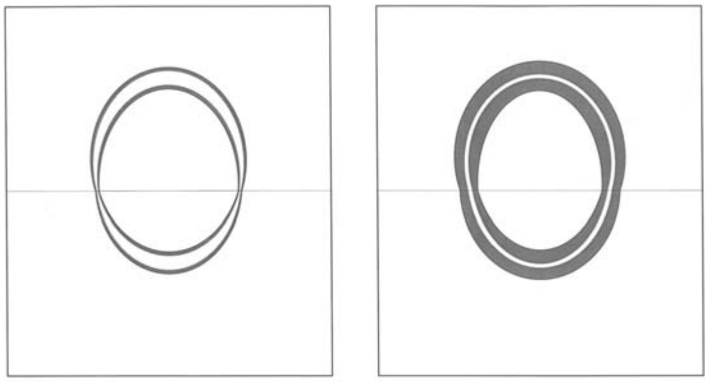
A single lune on two consecutive exposures. The partial reflections appear on both images and their intensity is distributed over both.



$\eta < \Delta\varphi$ $\eta \sim \Delta\varphi$

Figure 9.1.6.5
Appearance of a lune for (left) a crystal of low mosaicity and (right) a highly mosaic crystal. Characteristically, the width of the lune along the rotation axis is wider if the mosaicity is high.

single image, and these are referred to as fully recorded reflections, or fullys.

Other reflections will start to diffract during one exposure, but will still be diffracting at the end of the $\Delta\varphi$ rotation range. The remaining intensity of these reflections will be recorded on subsequent images. There will of course be corresponding reflections at the start of the present image. These reflections are termed partially recorded, or partials. Fig. 9.1.6.4 shows schematically how a lune appears on two consecutive exposures, with partials at each edge. The partials at the bottom edge of each lune contain the rest of the intensity of the partials from the previous exposure. The rest of the intensity of the partials at the top of the lune will appear on the next exposure. Superposition of two successive images will reveal some spots common to both: they are the partials shared between the two. If the angular spread ξ is small compared with the rotation range $\Delta\varphi$ then most reflections will be fully recorded. As ξ increases, the proportion of partials will rise, and when it reaches or exceeds $\Delta\varphi$ in magnitude there will be no fully recorded reflections. If the rotation range per image is small compared with the rocking curve, individual reflections can be spread over several images.

As ξ increases, the lunes become wider (Fig. 9.1.6.5), since there are more partial reflections crossing the Ewald sphere at any one time. The appearance of the lunes can be used to estimate the mosaicity of the crystal. If the edges are sharply defined, then the mosaicity is low. In contrast, if the intensities at the edges gradually fade away, then the mosaicity must be high. Indeed, this phenomenon can be exploited by the integration software to provide accurate definition of the orientation parameters and of the mosaicity.

A key characteristic of high mosaicity is that all lunes are wide in the region along the rotation axis. On still exposures, the width of the rings is proportional to the angular spread. The width of lunes is expected to be very small along the rotation axis. If they are wide in this region, this is especially indicative of high mosaic spread. While highly ordered crystals with low mosaicity are preferable and often lead to data of the highest quality, high mosaic spread is not a prohibitive factor in accurate intensity estimation, provided it is properly taken into account in estimating the data collection and integration parameters, such as individual rotation ranges.

9.1.6.6. The width of the rotation range per image: fine φ slicing

An important variable in the rotation method is the width of the rotation ranges per individual exposure. The two basic approaches can be termed wide and fine φ slicing, and differ in the relation between the angular spread and the rotation range per exposure. The two methods are applicable under different experimental constraints.

Fine φ slicing requires that the individual intensities are divided over several consecutive images, *i.e.* $\Delta\varphi$ should be substantially less than ξ (Kabsch, 1988). This approach possesses two very positive features. Firstly, it minimizes the background by integrating intensities only over a φ range equivalent to the rocking curve of the crystal. Secondly, it allows the fitting of 3D profiles to the pixels that compose a reflection, the first two dimensions being the *xy* plane of the detector and the third the φ rotation. In combination, these should provide an optimum signal-to-noise ratio for the measured intensities and would appear to be the method of choice for data collection.

However, this involves a very large number of images, which can pose logistical problems in terms of data handling. Only if the read-out time is negligible in comparison with the exposure time can fine slicing be applied. If the detector read-out is slow, fine slicing becomes totally impractical. Multiwire chambers allow fine φ slicing, but unfortunately their disadvantages in terms of effective dynamic range preclude their use on high-intensity sources. Imaging plates are generally too slow for this approach.

The fine-slicing method is likely to receive a resurgence of interest with the introduction of fast read-out detectors such as the PILATUS, where diffraction images can be acquired continuously without the use of a beam shutter (Hülsen *et al.*, 2006).

9.1.6.7. Wide slicing

The object of the wide-slicing approach is to acquire the data on as small a number of individual exposures as possible. It involves large $\Delta\varphi$ values per image, usually of the order of 0.5° or more, which exceed the angular spread. Each image contains a considerable proportion of fully recorded reflections. Originally, wide slicing was used to minimize the large numbers of X-ray films to be processed. Only the wide-slicing approach is tractable for detector systems where the read-out time is relatively slow in relation to exposure, *e.g.* imaging plates with read-out times of 20 seconds to minutes.

Wide slicing has two drawbacks. Firstly, during integration of the intensity data, only 2D profiles are fitted for each individual spot in the wide slicing. Secondly, each reflection profile overlaps a background which accumulates throughout the whole time and

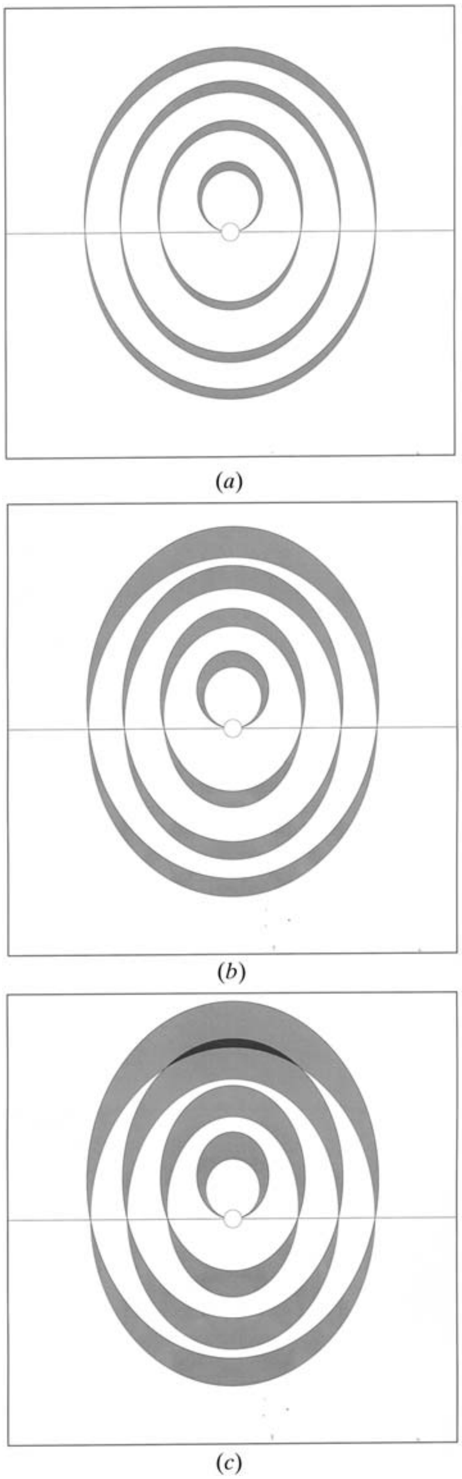


Figure 9.1.6.6
The width of the lunes is proportional to the rotation range per image, $\Delta\varphi$, which increases from (*a*) to (*c*). If the rotation range is large, the lunes overlap at high resolution.

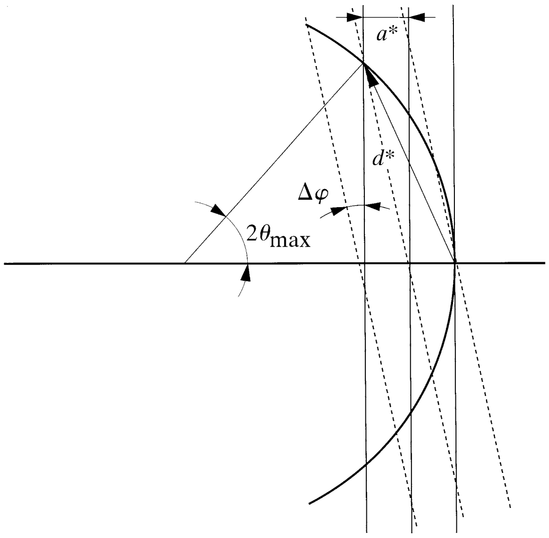

Figure 9.1.6.7
The largest allowed rotation range per exposure depends on the dimension of the primitive unit cell oriented along the X-ray beam; this is diminished by high mosaicity.

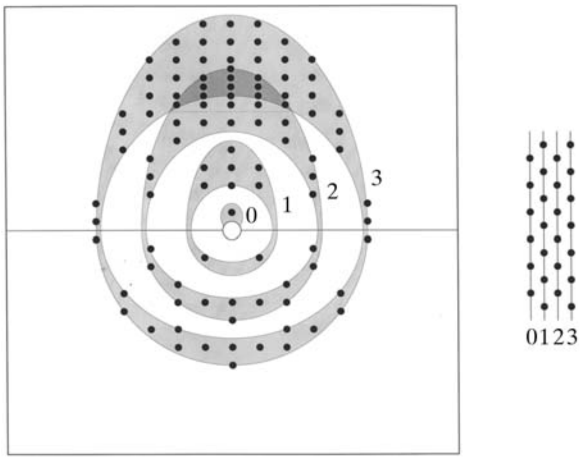

Figure 9.1.6.8
If the crystal lattice is centred or if its orientation is non-axial, the reflections do not overlap in spite of overlapping lunes, as illustrated on the right with consecutive layers of reflections viewed from the side.

angular range of the exposure, even when the reflection concerned is not diffracting.

The aim is to use the maximum acceptable rotation range per image. The lunes on an image have a finite width proportional to the rotation range. This width restricts the allowed angular range per image, as overlap of spots resulting from overlap of adjacent lunes must be avoided if the intensities are to be successfully integrated (Fig. 9.1.6.6). Several factors affect the degree of overlap and will be discussed in the rest of this section. A simple formula (Fig. 9.1.6.7) can be used to estimate the maximum permitted rotation range per image:

$$\Delta\varphi = 180d/\pi a - \xi,$$

where the factor $180/\pi$ converts radians to degrees, ξ is the angular spread of the reflection, d is the high-resolution limit and a is the length of the primitive cell dimension along the direction of the X-ray beam. However, this simplistic equation can be somewhat misleading. It most strictly applies when the lunes are densely packed with reflections, for an orthogonal cell rotated about a major axis. If this is not the case, then often rows of reflections from one lune fit between rows in the adjacent lune without overlap. For example, for a trigonal crystal with its *a* axis along the beam and rotating about its *c* axis, even and odd lunes contain rows of reflections that lie between one another on the detector (Fig. 9.1.6.8).

It can be extremely hard to record data from samples with a very long cell dimension. If the long axis lies along the X-ray beam, then it will restrict $\Delta\varphi$ considerably to very low values. This is exacerbated if the mosaicity is substantial. It is therefore beneficial to have the longest axis oriented roughly along the spindle axis, as it can then never lie parallel to the beam. This can be a problem with cryogenic samples mounted in loops, where the preferred orientation is hard to dictate, and this is an example where a κ-goniostat is an advantage, allowing reorientation of the crystal.

Simplistic application of the above equation for estimating $\Delta\varphi$ is not receommended. The degree of overlap also depends on pixel size, beam cross section, crystal size and mosaicity, and crystal-to-detector distance. Given the influence of these additional parameters, it is in practice better to employ the integration software first to interpret the diffraction pattern and to simulate predicted patterns by adjusting the data-collection parameters. Several modern packages have such strategy features, and it is vital to employ them before collecting data. In fact, from a theoretical point of view, the highest signal-to-noise ratio is obtained when $\Delta\varphi$ corresponds to the rocking curve of the diffraction, *i.e.* the mosaic spread plus the beam divergence.

9.1.7. Rotation method: geometrical completeness

This topic has been reviewed by Dauter (2005).

9.1.7.1. Total rotation range for non-anomalous data

The total set of structure-factor amplitudes from a crystal is a sphere of points in reciprocal space, with a radius defined by the maximum resolution. The intensities of the two hemispheres of data show a centrosymmetric relationship based on Friedel's law, which only breaks down if anomalous scatterers are present. However, the diffraction pattern possesses internal symmetry related to that of the real-space unit cell. This means that for all space groups an asymmetric unit of reciprocal space can be defined. Provided the intensities of all reflections in this asymmetric unit have been measured, those of all others can be generated by the symmetry operations and the Fourier transform for the complete structure computed.

The asymmetric unit has the shape of a wedge extending from the origin at the centre of the reciprocal sphere with a cutoff at a maximum radius corresponding to the limiting diffraction angle (resolution). Once the Laue symmetry group of the crystal has been determined (*International Tables for Crystallography*, Volume A, 2005), it is straightforward to define the shape of this wedge and establish which data must be recorded to make up a complete unique set. For macromolecular crystals, where there can be no centre of symmetry, the possibilities are further simplified to the point group rather than the Laue group. All space groups belonging to the same point group have the same asymmetric unit. The only differences lie in the presence or absence of screw axes or centring. Thus, space groups $P2_12_12_1$, $P2_12_12$, $P222_1$, $P222$, $I222$ and $I2_12_12_1$ all belong to point group (symmetry class) 222 and have the same asymmetric unit in reciprocal space. The only consequence of the presence of screw axes or lattice centring is to introduce systematic absences for some classes of reflection within this asymmetric unit of the point group.

It is usual to define the limits of the asymmetric unit by placing restrictions on the indices. For point group 222, the common conventional choice of limits on the reflection indices *hkl* is

$$0 \leq h \leq h_{\max}, \qquad 0 \leq k \leq k_{\max} \qquad 0 \leq l \leq l_{\max},$$

where $h_{\max}$, $k_{\max}$ and $l_{\max}$ are defined by the maximum resolution. In all point groups, there are multiple but equivalent ways of defining the asymmetric unit, but a default definition is generally chosen by the data-reduction software. For example, in triclinic symmetry, any hemisphere constitutes an asymmetric unit, and there are three typical choices of index limits:

$$0 \leq h \leq h_{\max}, \qquad \bar{k}_{\min} \leq k \leq k_{\max}, \qquad \bar{l}_{\min} \leq l \leq l_{\max},$$

or

$$\bar{h}_{\min} \leq h \leq h_{\max}, \qquad 0 \leq k \leq k_{\max}, \qquad \bar{l}_{\min} \leq l \leq l_{\max},$$

or

$$\bar{h}_{\min} \leq h \leq h_{\max}, \qquad \bar{k}_{\min} \leq k \leq k_{\max}, \qquad 0 \leq l \leq l_{\max}.$$

The standard choices of asymmetric unit taken from the *CCP*4 program suite (Collaborative Computational Project Number 4, 1994) are shown in Table 9.1.7.1.

The data are complete if the Ewald sphere has been crossed by all reflections in the asymmetric part of the reciprocal lattice. During data acquisition and reduction, all measured indices are conventionally transformed to this asymmetric unit of reciprocal space. Firstly, this allows merging of symmetry-equivalent measurements as appropriate. Secondly, it allows the completeness of the data to be assessed efficiently, using contributions from the whole sphere.

For all point groups, rotation of the crystal by 180° from any starting angle on the φ spindle axis is sufficient to provide a complete set of data (this is not sufficient if anomalous-dispersion measurements are required; see Section 9.1.7.2). Given such a total rotation, the redundancy of the measurements will increase with higher crystal symmetry. Thus, for a triclinic space group, the unique data will be measured almost twice on average (see the blind region below); for orthorhombic, eight times; for hexagonal class 6, 12 times; and for 622, 24 times. Redundancy is, in principle, advantageous, giving improved data quality (again see below), but it is generally possible to record complete unique data with a minimal overall rotation and correctly chosen starting angle on the spindle. It is of course necessary to determine the crystal orientation matrix, and this remains a vital part of the data-collection strategy. To minimize the effects of radiation

Table 9.1.7.1

Standard choice of asymmetric unit in reciprocal space for different point groups from the *CCP4* program suite

Point group	Index limits	
1	*hkl*: *hk*0: 0*k*0:	$l \geq 0$ $h \geq 0$ $k \geq 0$
2	*hkl*: *hk*0:	$k \geq 0, l \geq 0$ $h \geq 0$
222	*hkl*:	$h \geq 0, k \geq 0, l \geq 0$
4	*hkl*: 0*kl*:	$h \geq 0, k > 0, l \geq 0$ $k \geq 0$
422	*hkl*:	$h \geq k, k \geq 0, l \geq 0$
3	*hkl*: 00*l*:	$h \geq 0, k > 0$ $l > 0$
321	*hkl*: *hhl*:	$h \geq k, k \geq 0$ $l \geq 0$
312	*hkl*: *h*0*l*:	$h \geq k, k \geq 0$ $l \geq 0$
6	*hkl*: 0*kl*:	$h \geq 0, k > 0, l \geq 0$ $k \geq 0$
622	*hkl*:	$h \geq k, k \geq 0, l \geq 0$
23	*hkl*: *hkh*:	$h \geq 0, k > h, l > h$ $k \geq h$
432	*hkl*:	$h \geq 0, k \geq l, l \geq h$

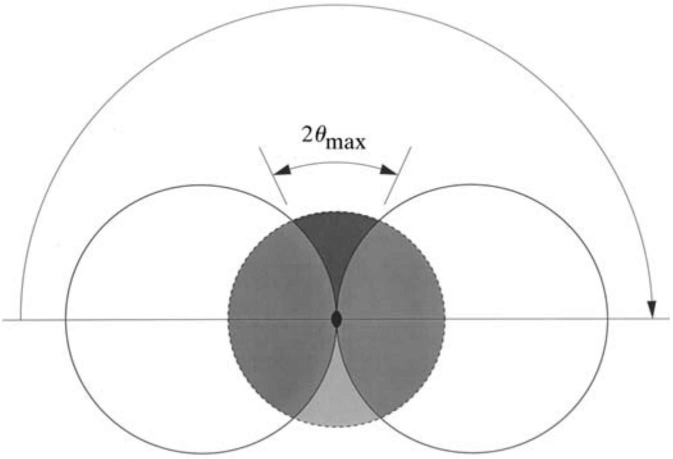

Figure 9.1.7.1
Rotation of a triclinic crystal by 180° in the X-ray beam, represented as rotating the Ewald sphere with a stationary crystal, projected along the rotation axis. For the purpose of analysing the relation of data completeness to crystal symmetry and orientation the two representations are equivalent.

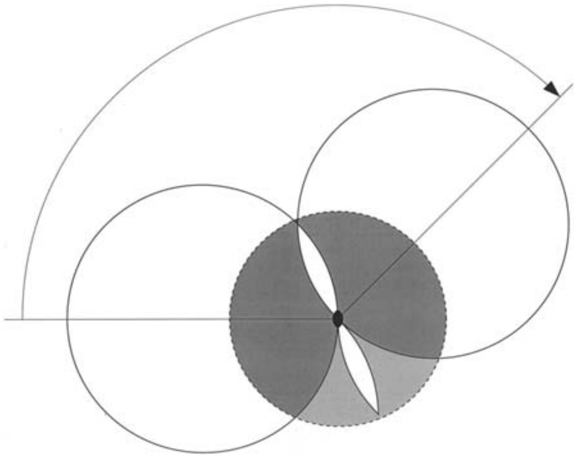

Figure 9.1.7.2
Rotation of a triclinic crystal by 135° is not sufficient to obtain totally complete data. At high resolution the completeness is higher than at low resolution, where a full 180° rotation is required.

damage, it is often beneficial to collect complete data with the minimal rotation range. This may well change with the advent of extremely fast detectors, when the decision-making process may take longer than data collection.

Thus, the crystal point-group symmetry has a profound effect on the total rotation range and the optimal starting spindle and crystal orientation for the most efficient recording of complete unique data. The rest of this section suggests strategies for the collection of complete data with minimal total rotation when anomalous-dispersion measurements are not required.

As stated above, for all crystals, rotation by 180° is sufficient to cover fully both sides of the Ewald sphere with intensity measurements. This is necessary for a triclinic crystal rotated around any arbitrary axis and also for a monoclinic crystal rotated around its unique *b* axis (Fig. 9.1.7.1). A twofold redundancy of unique data results; fourfold for the monoclinic case. Now consider a rotation of less than 180° (Fig. 9.1.7.2). Owing to the curvature of the Ewald sphere and the centre of symmetry arising from Friedel's law, the region of the sphere with reflections measured twice is diminished, and for part of the sphere there are no measurements. Most importantly, the proportions are resolution dependent. With a limited rotation, the high-resolution intensities reach a higher completeness than those at low resolution: data 90% complete at high resolution may be missing 20% of the low-resolution shells. Indeed, the low-resolution terms only become complete when a full 180° has been achieved.

The major data-processing software packages provide estimates of overall completeness as a function of total rotation range and starting point. However, they tend to neglect this variation with resolution. The fundamental importance of completeness at low resolution will be returned to later.

For total rotation by a given percentage of the angle needed to provide complete data, the resulting percentage completeness will be higher, again as a consequence of the curvature of the Ewald sphere. Consider again the triclinic case, when complete data require rotation by 180°. A single continuous range of 90° gives a completeness of about 65% (Fig. 9.1.7.3). Splitting the rotation range is advantageous; for example, if the crystal is rotated over two ranges of 45°, separated by a gap of 45°, the completeness typically rises to about 80%. In summary, for the triclinic case, the starting point and crystal orientation are irrelevant, but if it is impossible to cover 180° in the time available, it is better to use two or more sets of ranges. The software can again often provide advice on such strategies.

When the crystal has symmetry elements, the situation is more complex. Now the completeness is sensitive to the starting point of rotation and the crystal orientation, as well as the total rotation range used. All three must be considered in defining an optimum strategy for minimal rotation to give complete data. Consider an orthorhombic unit cell where the asymmetric unit comprises any octant of the reciprocal lattice. Minimal complete data require a total rotation of 90° between any twofold axis and the plane perpendicular to it (Fig. 9.1.7.4). This requires that one of the major axes must lie along the direction of the beam, either at the start or end of the 90° rotation, when the other two axes will lie in the plane of the detector. It is not necessary to rotate around one of the major axes, but the rotation axis should lie in one of the three major planes. If these conditions on crystal orientation or starting point are not satisfied, then more than a 90° rotation will be required. The proper selection of starting point is vital. A 90°

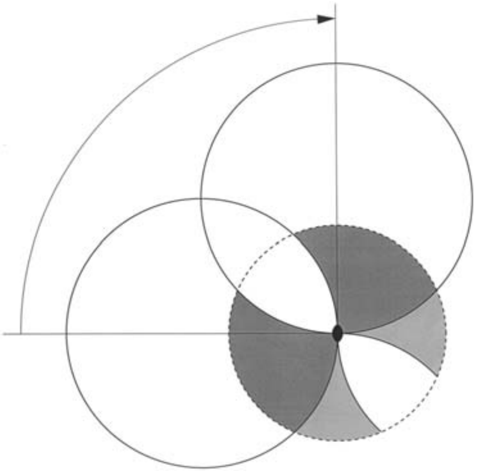

Figure 9.1.7.3
After a 90° rotation out of a required 180°, the overall completeness is higher than 50%.

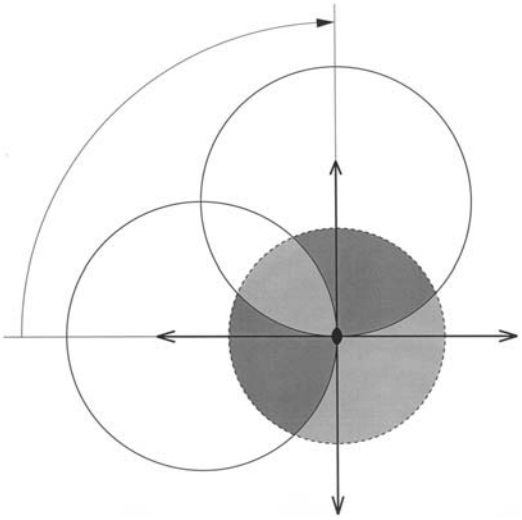

Figure 9.1.7.4
For an orthorhombic crystal, a 90° rotation is sufficient provided the starting or final orientation is along the major axis.

rotation starting midway between two axial positions, when the major axis only lies along the beam after 45°, will reduce the completeness after 90° to about 65%, since in essence the same 45° of unique data will be measured twice, albeit with high redundancy (Fig. 9.1.7.5). This emphasizes the need to define the crystal symmetry and orientation properly before data collection if minimalist protocols are to be employed.

In general, the higher the crystal symmetry, the more the completeness depends on the crystal orientation. In point groups 321 or 312, the asymmetric unit may be defined as a 30°-wide wedge that spans the space between the positive and negative direction of the threefold *c* axis. The index limits are

$$0 \le h \le h_{\max}, \qquad 0 \le k \le h, \qquad \bar{l}_{\max} \le l \le l_{\max}.$$

If the crystal is mounted with the threefold axis along the rotation spindle, it is sufficient to rotate by 30°, but only if the *a* or *b* axis lies along the beam at the start or end of the range. In contrast, if the crystal is rotated around **a** or **b**, then it is necessary to cover 90°. The second procedure will lead to a threefold increase in redundancy, but at the expense of a longer time.

The total rotation requirements for various crystal symmetries and orientations are given in Table 9.1.7.2. It is difficult to give reliable estimations for cubic crystals, since then the requirements vary dramatically with the crystal orientation.

Table 9.1.7.2
Rotation range (°) required in different crystal classes

The direction of the spindle axis is given in parentheses; *ac* means any vector in the *ac* plane.

Point group	Native data	Anomalous data
1	180 (any)	$180 + 2\theta_{\max}$ (any)
2	180 (*b*); 90 (*ac*)	180 (*b*); $180 + 2\theta_{\max}$ (*ac*)
222	90 (*ab* or *ac* or *bc*)	90 (*ab* or *ac* or *bc*)
4	90 (*c* or *ab*)	90 (*c*); $90 + \theta_{\max}$ (*ab*)
422	45 (*c*); 90 (*ab*)	45 (*c*); 90 (*ab*)
3	60 (*c*); 90 (*ab*)	$60 + 2\theta_{\max}$ (*c*); $90 + \theta_{\max}$ (*ab*)
32	30 (*c*); 90 (*ab*)	$30 + \theta_{\max}$ (*c*); 90 (*ab*)
6	60 (*c*); 90 (*ab*)	60 (*c*); $90 + \theta_{\max}$ (*ab*)
622	30 (*c*); 90 (*ab*)	30 (*c*); 90 (*ab*)
23	~60	~70
432	~35	~45

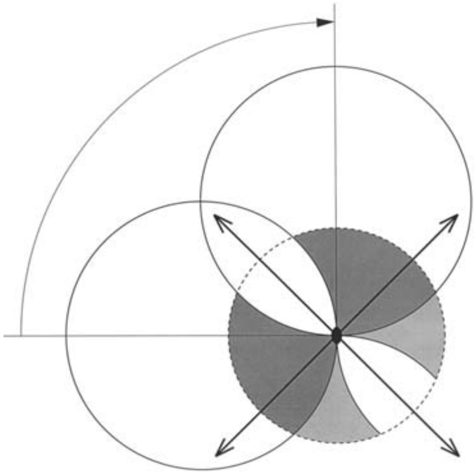

Figure 9.1.7.5
Rotation of an orthorhombic crystal by 90° between two diagonal orientations leaves a part of the reciprocal space unmeasured.

In the above, it was assumed that the detector was mounted centrally with respect to the incident X-ray beam. If it is offset either by a 2θ arm or by a translation, then the completeness for any total rotation range will be reduced. Software will generally be required to estimate the effective completeness and derive optimum strategies. For minimalist approaches to obtaining a high completeness, the importance of selecting the total rotation range, the optimal starting point and indeed the crystal orientation must be stressed. This means that the crystal orientation must be defined at the start of the experiment from the initial exposures.

9.1.7.2. *Total rotation range for anomalous-dispersion data*

In the presence of anomalous-scattering centres, Friedel's law breaks down and the intensities of the two halves of the reciprocal sphere are no longer equivalent. Strictly speaking, reflections related by a centre of symmetry or mirror relation cease to have equal intensities, but those related by pure rotation preserve their equivalence. The non-equivalent pairs of reflections are known as Bijvoet pairs. In macromolecular crystallography, it is often highly desirable to record the intensity differences between the Bijvoet mates to provide information on the position of anomalous scatterers, usually to be exploited in phasing procedures (Part 14). The anomalous signal should also be retained for so-called native data, for example in the discrimination between water and ions in the surface solvent shell.

This implies that the intensities of the unique reflections have to be measured for both hemispheres of reciprocal space. In the general (triclinic) case, this requires the rotation of the crystal by a wider rotation range. At very low resolution, the surface of the Ewald sphere can be approximated by a plane. In this case, rotation of the lower half of the Ewald sphere will cover a full hemisphere of data, and the upper half will cover the remaining centrosymmetrically related hemisphere. At high resolution, the surface of the Ewald sphere increasingly deviates from planarity by the Bragg angle θ on each side (Fig. 9.1.7.6). To record complete anomalous data for such a triclinic crystal therefore requires it to be rotated by $180° + 2\theta_{\max}$ from a random starting position. This will measure each Bijvoet mate at least once. However, only after a total rotation of 360° will the average multiplicity reach a value of two.

Similar reasoning applies to higher-symmetry space groups. Intensity data for two asymmetric units related by a centre of

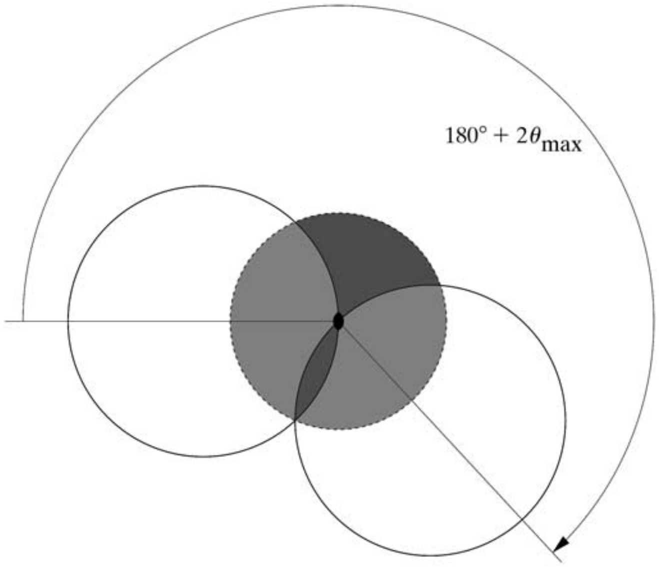

Figure 9.1.7.6
For data containing an anomalous signal, when both Bijvoet mates have to be measured, 180° rotation of a triclinic crystal is not sufficient and at least an additional $2\theta_{\max}$ is required.

symmetry or a mirror need to be recorded. For some cases, the total range remains the same for completeness of anomalous data as for native. However, in several symmetries or orientations, the total range must again be increased by either $\theta_{\max}$ or $2\theta_{\max}$ (Table 9.1.7.2).

9.1.7.3. Blind region

Even after rotation of the crystal about a single axis by 360°, some reflections do not cross the surface of the Ewald sphere and cannot be measured. These lie in a cusp around the rotation axis which is referred to as the blind region. This is in principle a disadvantage of the single-rotation method, but for most systems the problems are easily overcome. Owing to the curvature of the Ewald sphere, the width of the blind region increases with the resolution and directly depends on a single parameter, the diffraction angle θ (Fig. 9.1.7.7). The fraction, B_θ, of unrecordable reflections lying in the blind region at a particular resolution with Bragg angle θ is given by

$$B_\theta = 1 - \cos\theta.$$

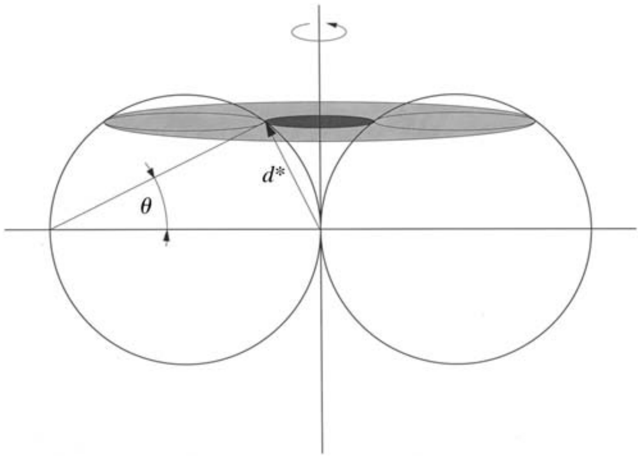

Figure 9.1.7.7
Rotation by 360° leaves the part of the reciprocal space in the blind region unmeasured, since the reflections near the rotation axis do not cross the surface of the Ewald sphere. The rotation axis in this projection lies vertically in the plane of the figure.

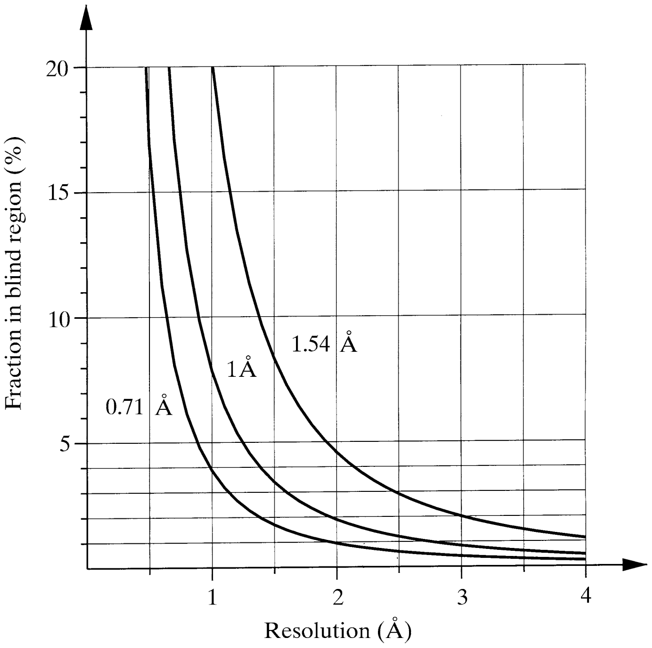

Figure 9.1.7.8
Dependence of the total fraction of reflections in the blind region on the resolution for three different wavelengths: 1.54, 1 and 0.71 Å.

The cumulative fraction, $B_{\rm tot}$, of reflections in the blind region up to a certain resolution is given by

$$B_{\rm tot} = 1 - 3(4\theta - \sin 4\theta)/(32\sin^3\theta).$$

$B_{\rm tot}$ is shown graphically as a function of resolution for selected wavelengths in Fig. 9.1.7.8.

For a particular resolution limit, the blind region is narrower if the wavelength is short, since the surface of the Ewald sphere is flatter (Fig. 9.1.7.9). This is an advantage of using short-wavelength radiation. For Cu $K\alpha$ radiation at 2.0 Å resolution, the blind region amounts to less than 5%. With shorter wavelengths, it falls below 2%.

The two halves of the blind region on either side of the Ewald sphere are related by the centre of symmetry. In the triclinic case, the blind region is therefore unavoidable with a single mount of

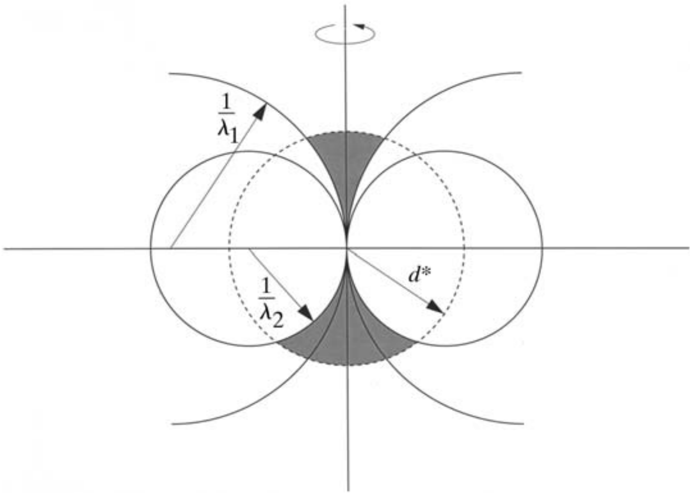

Figure 9.1.7.9
For shorter wavelengths the blind region is narrower, since the Ewald sphere is flatter.

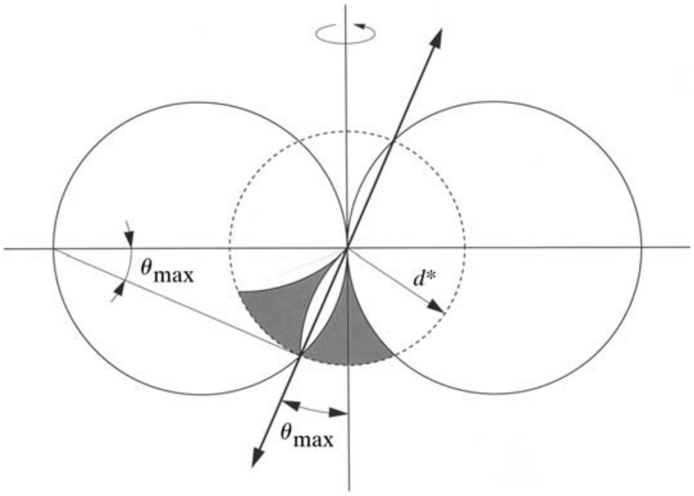

Figure 9.1.7.10
If the crystal has a symmetry axis, it should be skewed from the rotation axis by at least $\theta_{\max}$ to be able to collect the reflections equivalent to those in the blind region.

the crystal. The only solutions are to use a second mount of the crystal offset by at least 2θ from the first, easily achievable with a κ-goniostat, or to measure from a second sample.

For crystals with symmetry higher than $P1$, reflections that are symmetry-equivalent to those in the blind region may be recorded, and there will be no loss of unique reflections. Only if the unique axis passes through the blind region approximately parallel to the spindle axis will the reflections lying close to it not be repeated by symmetry in another region of reciprocal space. To avoid the blind region, it is sufficient to misorient the unique symmetry axis by at least $\theta_{\max}$ from the rotation axis (Fig. 9.1.7.10). To achieve full completeness, monoclinic crystals should not be oriented along the unique twofold axis or along any vector in the *ac* plane.

The reciprocal-lattice points on the border of the blind region cross the surface of the Ewald sphere at a very acute angle or fail to cross it completely, staying in the diffracting position for a considerable time. Their intensity cannot be measured accurately, because the Lorentz factor is large and its magnitude is very sensitive to minor errors in the orientation matrix. These reflections are located on the detector window along the line parallel to the spindle axis and should not be integrated.

The detrimental effect of the blind region on the completeness of data is negligible at medium and low resolution or if the crystal is non-axially oriented. This means that a simple single rotation axis is sufficient for the majority of applications.

9.1.7.4. *Alternative indexing*

If the crystal point-group symmetry is lower than the symmetry of its Bravais lattice, then the reflections can be indexed in more than one way. In other words, the symmetry of the reflection positions is higher than the symmetry of the distribution of their intensities. This situation typically arises for point groups with polar axes, such as groups 3, 4 or 6, which can be indexed with the *c* axis pointing in either one of two directions. The lattice does not define the directionality of such axes if its two remaining cell dimensions are equivalent. This problem does not occur in the monoclinic system, despite the polar twofold axis, as the two other axes are not equivalent. The most complex case is point group 3, which can be indexed in the 622 lattice in four non-equivalent ways. The other such groups have only two alternatives.

Table 9.1.7.3
Space groups with alternative, non-equivalent indexing schemes

Symmetry operations required for re-indexing are given as relations of indices and in the matrix form. In brackets are the chiral pairs of space groups indistinguishable by diffraction. These space groups may also display the effect of merohedral twinning, with the twinning symmetry operators the same as those required for re-indexing.

Space group	Re-indexing transformation	
$P4$, $(P4_1, P4_3)$, $P4_2$, $I4$, $I4_1$	$hkl \rightarrow kh\bar{l}$	$010/100/00\bar{1}$
$P3$, $(P3_1, P3_2)$	$hkl \rightarrow \bar{h}\bar{k}l$	$\bar{1}00/0\bar{1}0/001$
	or $hkl \rightarrow kh\bar{l}$	$010/100/00\bar{1}$
	or $hkl \rightarrow \bar{k}\bar{h}\bar{l}$	$0\bar{1}0/\bar{1}00/00\bar{1}$
$R3$	$hkl \rightarrow kh\bar{l}$	$010/100/00\bar{1}$
$P321$, $(P3_121, P3_221)$	$hkl \rightarrow \bar{h}\bar{k}l$	$\bar{1}00/0\bar{1}0/001$
$P312$, $(P3_112, P3_212)$	$hkl \rightarrow \bar{h}\bar{k}l$	$\bar{1}00/0\bar{1}0/001$
$P6$, $(P6_1, P6_5)$, $(P6_2, P6_4)$, $P6_3$	$hkl \rightarrow kh\bar{l}$	$010/100/00\bar{1}$
$P23$, $P2_13$, $(I23, I2_13)$, $F23$	$hkl \rightarrow k\bar{h}l$	$010/\bar{1}00/001$

There is an analogous problem for cubic space groups within point group 23. Here the lattice possesses fourfold symmetry, but the intensity distribution has only twofold symmetry. Rotation by 90° leads to alternative, although perfectly permitted, indexing of reflections.

Each allowed scheme is permitted and self-consistent for a single crystal, since all possibilities will perfectly match the crystal lattice. However, under alternative indexing schemes, the same reflection will be given different indices, which can pose problems when data from more than one crystal are to be merged or compared. Merging is needed when more than one sample is required to record a complete data set. Comparison is needed when looking for heavy-atom derivatives or for ligand complexes with isomorphous crystals. For these, the reflections of one crystal must be selected as a standard, and it is easy to make other crystals consistent with this standard either by changing the orientation matrix at the time of intensity integration or by applying re-indexing to the integrated intensity set. The alternative indexing schemes are related by those symmetry operations present within the higher symmetry of the Bravais lattice but absent from the point-group symmetry. The point groups with alternative indexing systems are shown in Table 9.1.7.3, together with the necessary symmetry operations for re-indexing.

Several experiments require the recording of multiple data sets from the same crystal. One example is the collection of more than one pass with different exposure times (see below), and a second is in multiwavelength anomalous dispersion (MAD) experiments. In these experiments, the software systems may independently choose any of the alternative systems for different sets, which may then be incompatible and need re-indexing. It is much simpler to ensure a common orientation matrix modified as appropriate for all sets at the time of intensity integration.

9.1.8. Crystal-to-detector distance

The crystal-to-detector distance (CTDD) should be selected so that the whole area of the detector is usefully exploited. The shorter the CTDD, the higher the resolution of the indexed reflections at the edge of the image; but if the CTDD is too short, then the outer regions of the detector window record only indices with attached noise rather than intensities. A longer CTDD spreads the background radiation over a larger area of the detector as the background level diminishes in proportion to the square of the CTDD. In contrast, owing to collimation and focusing, the profiles of the Bragg reflections do not broaden so much, and the signal-to-noise ratio is enhanced at longer distances. It is advantageous to use the largest possible CTDD under the condition that meaningful data extend to, but not beyond, the active edge of the detector.

It is not straightforward to judge the resolution limit of meaningful diffraction. The most scientific approach involves recording, processing and merging a small number of images and making a decision on the basis of the resulting intensity statistics. However, this does require time, which should only pose a problem on ultra-high-intensity sources with very rapid data collection. A more pragmatic approach relies on visual inspection of the initial exposures using a graphical display at various contrast levels. Normally, if reflections are not visible by eye at the highest display contrast, their intensities are not meaningful. Some safety margin can be applied by setting the CTDD to a slightly shorter value than that estimated from visual inspection. Naturally, the resolution limit to which meaningful intensities extend depends on the exposure time, and the decision concerning the CTDD should follow the selection of the appropriate exposure (Section 9.1.11.2).

In addition to the significance of the reflection intensities, another important factor is the spatial resolution of spot profiles on the detector. If the crystal cell dimensions are large, the profiles may superimpose and the reflections may be impossible to integrate. At longer CTDD, the diffraction pattern spreads out and the profile overlap diminishes. If necessary, the detector can be offset from the central position to measure high-resolution data at long CTDD, but a larger total rotation is required to reach full data completeness. This applies only if the overlap of profiles belonging to the same lune results from a long axis lying parallel to the detector plane. The superposition of reflection profiles resulting from overlapping lunes will not be alleviated by increasing the CTDD; the only remedy for this is to reduce the rotation range $\Delta\varphi$ per exposure.

In addition to the proper selection of the CTDD, attention should be paid to the proper positioning of the beam stop. It should be centred with respect to the direct beam and cover the beam cross section completely. No part of the direct beam should reach the detector, and there should be no indirect scatter by the beam stop. The optimal reduction of air scatter is to have the smallest beam stop consistent with the dimensions of the beam, placed as close to the crystal as possible. For a given size of beam stop, the crystal-to-beam stop distance should be matched to the CTDD, sufficiently far from the crystal to minimize its shadow and concomitant obstruction of the valuable lowest-resolution reflections. If the beam stop is mounted on a metal wire, it is better to position the wire along the spindle axis where it will only interfere with those reflections around the blind region.

9.1.9. Wavelength

The wavelength of X-radiation can be tuned only at synchrotron sources. Rotating-anode generators produce radiation at a fixed wavelength which is characteristic of the metal of the anode, usually copper with $\lambda = 1.542$ Å.

The proper selection of the wavelength is most important for collecting data containing an anomalous-scattering signal. In general, the imaginary component $\Delta f''$ of the anomalous-dispersion signal is high on the short-wavelength side of the absorption edge of the anomalous scatterer present in the crystal. Near the absorption edge, both components, real $\Delta f'$ and imaginary $\Delta f''$, vary significantly. This variation is utilized in the MAD technique, the strict requirements of which are discussed in Chapters 14.2 and 14.3.

If the data are collected using a single wavelength with the aim of measuring Bijvoet differences, $\Delta F_{\rm anom} = F^{+} - F^{-}$, the requirements are not as strict as for MAD. However, it may be advisable to record the fluorescence spectrum around the region of the expected absorption edge. If the fluorescence signal from the crystalline sample is too weak, the appropriate metal or salt standard can be used. When using anomalous scatterers displaying large white lines within their spectra, the wavelength should be accurately adjusted on the basis of the spectrum measured from the actual sample.

For collecting data without an anomalous signal, there are no strict requirements concerning the wavelength. The maximum intensity provided by the beamline depends on the energy of particles in the synchrotron storage ring and on the beamline optics. Typically, wavelengths around 1 Å or shorter are used at most synchrotrons, assuring high beam intensity and low absorption of X-rays by the sample and air, thus reducing the radiation damage of the crystal. This is of particular importance at the very bright beamlines at third-generation synchrotrons. To diminish the effect of air absorption further, it is possible to fill the space between the crystal and the detector with helium. Short wavelengths are advantageous for collecting high-resolution data, since the diffraction angles are smaller and there is no need to use a very short CTDD. The effect of profile elongation owing to the oblique incidence of diffracted X-ray beams on the detector is then smaller, and the blind region is narrower.

9.1.10. Lysozyme as an example

Tetragonal hen egg-white lysozyme (Chapter 25.1 and Blake *et al.*, 1967), crystallizing in the space group $P4_32_12$ with cell dimensions $a = b = 78.6$ and $c = 37.2$ Å, is used here as a model system to illustrate some of the points made above, based on Dauter (1999). The example involves a set of two consecutive blocks of images with a crystal-to-detector distance of 243 mm, a wavelength of 0.92 Å, a resolution of 2.7 Å, an oscillation range of 1.5° and a crystal mosaicity around 0.5°. These images are shown in Fig. 9.1.10.1(*a–f*).

The first four images, (*a–d*), were exposed with the tetragonal fourfold *c* axis lying approximately along the direction of the beam. On these images, the reflections within each lune are arranged in a square grid, reflecting the tetragonal symmetry with $a = b$. The squares are oriented with their diagonals in the horizontal and vertical directions of the image, as the crystal was mounted with its [110] direction along the spindle rotation axis. Indeed, at the end of image (*a*) and the start of image (*b*), the *c* axis lay almost perfectly along the beam, and the zero-layer lune almost disappears behind the beam-stop shadow, since the corresponding (*hk*0) plane in reciprocal space is tangential to the Ewald sphere at the origin of the reciprocal lattice.

The lunes are widely spaced with clear gaps between them, because the third cell dimension, *c*, which is perpendicular to the detector plane, is relatively short, 37.2 Å. Images (*e–f*), exposed at an angle on the rotation spindle roughly 90° away from (*a–d*), have a quite different appearance, despite the rotation range per image being the same. Each lune is less densely populated by reflections, but the number of lunes is larger and the gaps between them much smaller. This arises from the lunes now being parallel to the (*hhl*) family of planes, as the $[1\bar{1}0]$ vector is now parallel to the beam. The interplanar spacing within this family is less than for those on images (*a–d*), hence at high resolution,

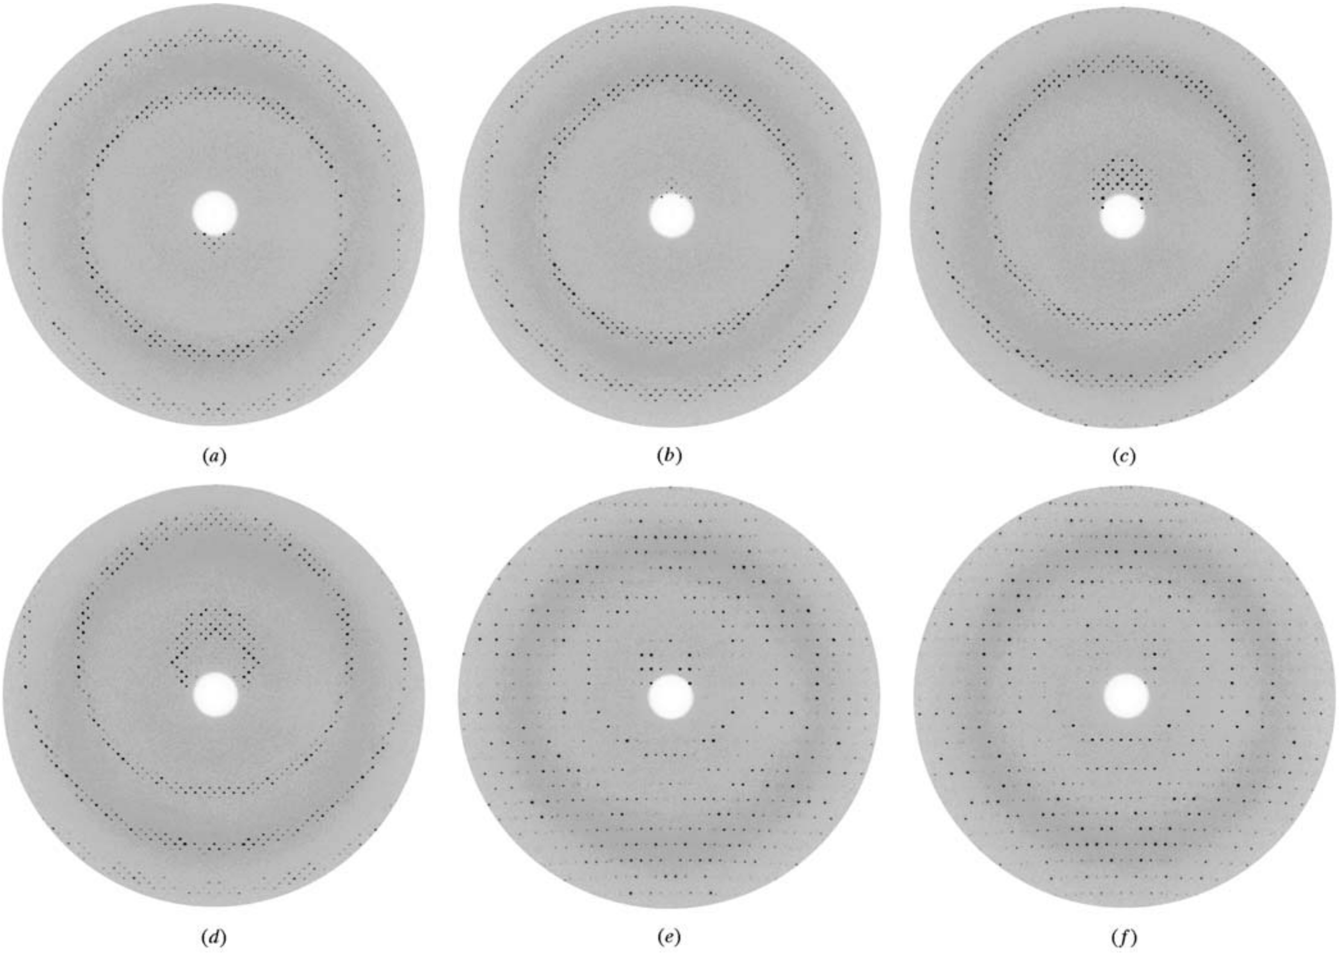

Figure 9.1.10.1
Images recorded from a crystal of lysozyme. (*a*–*d*) Four consecutive exposures with the crystal fourfold axis parallel to the X-ray beam. (*e*–*f*) Two successive exposures 90° away, when the fourfold axis lies vertically in the plane of the image. The crystal [110] direction is parallel to the rotation axis, horizontal in the plane of the images.

close to the edge of the detector window, the lunes overlap on images (*e*–*f*). The reflections, however, do not overlap, as the crystal orientation is diagonal; the lunes are sparsely populated, with large separation between adjacent spots, so the reflections on successive lunes fit between one another. It should be noted that the density of reflections in different regions of the reciprocal lattice is constant, and that the total number of reflections recorded on an image depends only on the rotation range, not on the crystal orientation.

The zero-layer lune containing reflections with indices $hk0$ is especially evident on exposures (*c*–*d*) directly above the centre of the image. With such a lune close to the centre, the reciprocal lattice shows minimal distortion owing to its projection onto the detector plane, and the lune appears as a 'pseudo-precession' pattern. The systematic absence of every second reflection, with odd index, along the $h00$ and $0k0$ lines indicates the presence of twofold screw axes of symmetry along the crystal axes a and b. Images (*e*–*f*), 90° away, have the hhl lune at the centre and, although it is less well separated from higher lunes, the presence of a fourfold screw axis along $\mathbf{c}$ is confirmed by the presence of only every fourth reflection on the $00l$ line. This allows the identification of the space group as $P4_12_12$ or its enantiomorph, $P4_32_12$. In general, the positions of the reflections define only the Bravais lattice, and it is the symmetry of the intensity pattern which reflects the point group. Thus, further confirmation that the symmetry belongs to point group $P422$ rather than $P4$ comes from the symmetric relation of the intensity distribution on either side of each lune in images (*a*–*d*). This is equivalent to the earlier use of precession photography for space-group elucidation.

Close inspection shows that the reflections at the edges of the lune are also present on the adjacent image. The rotation range was 1.5°, and the mosaicity was estimated at 0.5°, and thus about one-sixth of the reflections are partially recorded at each edge of the lune, giving one-third partially recorded terms in total. The lack of sharpness at the edge of the lunes confirms a substantial level of mosaicity.

9.1.11. Rotation method: qualitative factors

9.1.11.1. Inspection of reflection profiles

Reflection profiles should be checked on the first recorded images. Very often a quick inspection of the profiles can disqualify a bad crystal without further loss of time. The profiles should have a single maximum and smooth shoulders. If the crystal shape is irregular, it may be reflected in the spot profile. Profiles should not have double maxima or be substantially elongated or smeared out, which usually arises from crystal splitting. The profiles should certainly be inspected if initial autoindexing of the diffraction pattern is unsuccessful.

Even if the spot profiles appear to be regular on the first image, it is good practice to inspect a second image at a substantially different φ rotation angle, preferably 90° away, since crystal splitting may have a similar effect on the appearance of the lunes and profiles as does high mosaicity on a single image (Section

9.1.6.3). High mosaicity and splitting (often incorrectly referred to as twinning) must not be confused. If two parts of a split crystal are slightly rotated with respect to one another around a certain axis, the diffraction patterns will look different depending on the orientation. When such an axis is perpendicular to the detector plane, the spots will be doubled or smeared out. When the axis is parallel to the detector plane, the profiles resulting from the two parts of the crystal will overlap almost perfectly, but the lunes will be broadened, similar to the effect of high mosaicity.

After indexing the diffraction pattern, the integration profiles should be matched with the size and shape of the diffraction spots. The spots should not extend into the area defined as background. Selection of integration profiles that are too small will lead to incorrect integration of intensities. In contrast, if the profile areas are too large then the standard uncertainties will be wrongly estimated.

9.1.11.2. Exposure time

According to the principles of counting statistics, the longer the exposure, the better the signal in the data. The standard uncertainty of the measurement is equal to the square root of the number of counts, and the signal-to-noise ratio increases with the accumulated counts. In practice there are limitations to this rule.

The dynamic range and saturation limit of the detector is one limiting factor. It may be impossible to measure adequately the strongest as well as the weakest reflection simultaneously, since their intensities differ by several orders of magnitude. If the exposure time is long enough to record the weakest intensities, then in general at low resolution the most intense reflections may saturate some pixels within their profile on the detector. Such reflections are termed ‘overloads’ and this problem will be addressed in Section 9.1.11.3.

Exposure time can be limited by the total time available for the experiment. This is often a particularly acute problem for synchrotron-data collection, with high oversubscription of beamlines. The decisions concerning exposure time depend on the expected application of the data, since different applications have different requirements, as addressed in Section 9.1.13. Within the given time constraints, the first priority should be data completeness, even at the expense of underexposure. In this context, it is useful to recall that to increase the statistical signal-to-noise ratio by a factor of two, it is necessary to prolong the exposure time by at least a factor of four.

9.1.11.3. Overloads

Some detectors, or their associated read-out systems, are limited in the number of counts they can accumulate in one pixel. The number recorded reaches a maximum number which cannot be further increased, *i.e.* the pixels can become saturated. This means that these pixels retain the same maximum value on longer exposure whilst other, non-saturated, pixels continue to accumulate counts. The intensity in saturated pixels will hence be underestimated compared to the others and any intensities estimated from profiles including such pixels will be biased towards low values. It is essential that pixels that are saturated are flagged and recognized by the processing software. There are several ways to deal with the problem of saturation.

(1) Reject all reflections that contain saturated pixels. These will tend to be at low resolution. If more than a very few are rejected, this can be a truly disastrous choice, especially if the data are to be used for molecular replacement. In addition, missing the largest terms degrades the continuity and information content of all electron-density maps derived therefrom. This point is relevant to several applications (Section 9.1.13).

(2) Reject only those pixels that are saturated, and fit average standard profiles estimated from the non-saturated spots. This gives a poorer estimate than if the pixels were not saturated, but for applications such as molecular replacement or direct methods where the high-intensity data are essential it is certainly better than option (1).

(3) Reduce the exposure time to ensure that there are no overloaded pixels. This is a trade-off, because if there is a large contrast between the intensity of the weakest and the strongest terms in the pattern, then the weaker terms will have a low and possibly unacceptable signal-to-noise ratio under this regime.

(4) Use more than one pass through the rotation range, with different exposure times. The longest exposures should be sufficient to ensure that the intensities of the data at the high-resolution limit of the pattern are statistically significant. The shortest should ensure that the number of saturated pixels in the ‘low-resolution’ pass is minimized. If the contrast between the low- and high-resolution passes is too great, differing by a factor of much more than about ten, then additional passes with intermediate exposure times should be used to allow satisfactory scaling of the data from these images. The CTDD for each pass with shorter exposure should be increased only so as to cover the resolution to which reflections were saturated on the previous pass. The rotation range on individual images can then be increased accordingly, in the wide φ-slicing option. On bright synchrotron beamlines, if the second pass requires exceedingly fast rotation of the spindle-axis motor and rapid opening and closing of the beam shutter beyond the limit of reliability, it may be better to attenuate the beam, for example with a series of aluminium foils. As discussed in Section 9.1.7.1, if high-resolution data are collected in several passes with different exposures and resolution limits, it may not be necessary to cover all of the theoretically required rotation range in the highest-resolution pass. The curvature of the Ewald sphere results in the high-resolution data being completed with a smaller total rotation range than the low. It is vital that the lowest-resolution pass covers the total rotation range required for complete data.

Clearly, the optimum solution is to have a detector with a sufficient dynamic range to cover pixels of both weak and strong reflections. The dynamic range has already been increased with recent imaging plates and CCDs. Enhanced dynamic range may prove to be the most important advance of solid-state pixel detectors.

An additional advantage of the fine-slicing approach is that it leads to fewer overloads. Each reflection profile is divided between several separate images and as a result the effective dynamic range of the detector is increased.

9.1.11.4. R factor, $I/\sigma(I)$ ratio and estimated uncertainties

It is customary to judge data quality by the overall $R_{\rm merge}$, calculated using the squares of the structure-factor amplitudes (often erroneously called intensities):

$$R_{\rm merge}=\sum_{hkl}\sum_{i}|I_{hkl,i}-\langle I_{hkl}\rangle|/\sum_{hkl}\langle I_{hkl}\rangle.$$

$R_{\rm merge}$ provides a measure of the distribution of symmetry-equivalent observed intensities around the average value. However, the most popular form of $R_{\rm merge}$ given above is not a proper, statistically valid quantifier. It does not take into account the multiplicity of the measurements and, as a consequence, it actually rises with increased multiplicity, falsely indicating degradation of the data quality when in reality they have a higher accuracy. Modifications of $R_{\rm merge}$ have been proposed to include the effect of multiple measurements properly (Diederichs & Karplus, 1997; Weiss, 2001) (see Chapter 2.2).

A better quantity for assessing the quality of the X-ray data is the $\sum_{hkl} I_{hkl}/\sum_{hkl}\sigma(I_{hkl})$ ratio, provided the standard uncertainties, $\sigma(I)$, are correctly estimated. Detectors such as imaging plates or CCDs do not measure individual X-ray quanta directly, having a gain factor dependent on the response of the individual detector pixel to a single X-ray photon. If the gain factor is not known accurately for a particular detector, the resulting standard uncertainties of the measured intensities will be estimated at an incorrect level. If the multiplicity of the reflections is higher than unity, it is possible to correct the uncertainties *a posteriori*. This can be done either from a comparison with the expected values using the χ^2 test, or by using the *t*-plot. The latter requires that the ratio of the differences between equivalent intensity measurements to their standard uncertainties, $t = (I_i - \langle I \rangle)/\sigma(I_i)$, follows a normal distribution with a mean of 0.0 and standard deviation of 1.0. Both of these methods assume the errors have a normal distribution, and that only the mean and width have been incorrectly estimated and should be appropriately adjusted. They cannot take into account systematic errors of measurement.

The data-merging procedure in addition allows the identification of statistical 'outliers' and their exclusion from the data (Read, 1999). Outliers are defined as those observations that lie sufficiently far from the mean of a set, and assumption of a normal distribution suggests they suffer from substantial systematic errors of measurement. In a crystallographic experiment, outliers are those intensity measurements that deviate unexpectedly from the mean intensity of a set of symmetry-equivalent reflections. In the recording of rotation data, one typical source of such systematic errors is erroneous classification of reflections predicted as partially or fully recorded. This is a severe problem for those reflections lying close to the blind region. A second example is the presence of so-called 'zingers' in individual CCD detector pixels caused by scintillations from trace radioactivity of the taper glass. Other problems such as shadowed or inactive regions of the detector window give rise to a range of such systematic errors.

A small number of outliers may be expected from such causes. However, the total fraction of reflections flagged as outliers and rejected from the merging process should be small, certainly much less than 1%. Larger fractions indicate serious deficiencies in the hardware or the software and suggest something is very wrong with the experiment. There should always be a physical reason for rejecting outliers, other than just a need to reject those agreeing poorly with their symmetry-equivalent intensities in order to drive down $R_{\rm merge}$. It is always possible to reduce $R_{\rm merge}$ and to provide an apparent 'improvement' in the data by rejecting a large percentage of measurements, but this is extremely bad practice.

Good crystallographic data depend strongly on an appropriate statistical procedure. It is also inappropriate to exclude those reflections with intensities lower than a cutoff limit, such as 1σ, before or during the process of data merging. Weak intensities also carry information and their neglect introduces bias into the measured intensity distribution, affecting, for example, the overall or individual atomic temperature factors.

The true outer resolution limit of the diffraction pattern is not trivial to define and indeed depends to some extent on the application. If $I/\sigma(I)$ is higher than 1.0, then a resolution shell of data indeed contains some information in a statistical sense – provided of course that $\sigma(I)$ has been correctly estimated. However, as $I/\sigma(I)$ falls close to unity there will in practice be very few significant observations amongst a great deal of noise. It is necessary to make some decision about where to cut the effective resolution. For the application of direct methods, for example using *SHELXD* (Sheldrick, 2008), the cutoff is often defined as the resolution shell where $I/\sigma(I)$ falls to 2.0, when $R_{\rm merge}$ usually reaches 20–40% depending on the symmetry and redundancy. Cruickshank (1999*a*,*b*) has provided a formula for a data precision indicator (DPI) which includes the effect of falling $I/\sigma(I)$ ratio (see Chapter 2.2).

For other applications it may be advisable to accept even very weak data. Direct methods use only a subset of the most meaningful reflections, but which should extend to as high a resolution as possible. In addition, when the data are sparse from crystals that only diffract to very limited resolution, perhaps around 3 Å, then it is essential to retain all the experimental data, even if they are weak.

9.1.12. Radiation damage

9.1.12.1. Historical perspective

All crystals irradiated with X-rays absorb at least a fraction of the radiation, resulting in damage to the sample (Henderson, 1990). The energy from the absorbed photons may initially result in the disruption of chemical bonds, before being eventually dissipated as thermal energy. For well ordered small-molecule crystals the lattice is close-packed and the effects arising from the absorbed photons are restricted to the immediate environment of the absorption event, so-called primary damage. Only when a substantial fraction of the crystal has been affected do cooperative effects set in.

In contrast, roughly 50% of a macromolecular crystal is disordered aqueous solvent (Matthews, 1968). At room temperature this allows a secondary mechanism of radiation damage, resulting from diffusion of radicals and ions produced at the primary absorption site which affect chemical moieties at positions remote from this site. The details of this process remain poorly understood but are related to the extremely damaging effects of X-rays on biological tissue. A consequence of this damage is that degradation of the crystal order continues even after the irradiation is stopped or interrupted. For collection of data at room temperature from protein crystals mounted in capillaries, secondary damage contributes significantly to the rate of deterioration of the diffraction pattern. One of the gains of the early applications of SR was that it allowed recording of data to proceed ahead of the effects of secondary damage, increasing the effective, if not the absolute, lifetime of the crystal in the X-ray beam. An experiment often required several crystals, all of which showed the effects of temporal decay in their recorded intensities, which needed to be merged to provide complete data.

9.1.12.2. Cryogenic vitrification

In the early 1990s, the introduction of protein-data collection at cryogenic temperatures, using so-called flash cooling, was a major breakthrough (Garman & Schneider, 1997; Rodgers, 1997;

Garman & Owen, 2006). Such vitrification of crystals largely prevented the effects of secondary damage. On the X-ray sources then available, it was in most cases possible to record complete data from a single sample without significant degradation of the diffraction, enormously simplifying the strategy of data collection and merging.

Almost all data are currently collected from vitrified samples (see Part 10). The prolonged life of the sample and modest rates of data acquisition, even at second-generation SR sources with imaging plates, allow enough time for careful analysis of the initial images and optimization of the strategy.

A second major advantage of cryogenic data collection is that it allows crystals to be reused after initial data have been recorded. Two examples show the usefulness of this approach. Firstly, when screening the binding of heavy atoms for phase determination or ligands for complex formation, data can first be recorded to the minimum resolution needed to determine whether the binding is successful. Secondly, a series of vitrified crystals can be screened for their degree of order in the home laboratory, and the best stored and retained for subsequent improved collection either in the home laboratory or at a synchrotron site. The ability to transport vitrified crystals has proved invaluable in this respect, and leads to optimal use of synchrotron resources.

9.1.12.3. High-intensity third-generation SR sources

The advent of third-generation SR sources and insertion devices has led to X-ray beams of unprecedented intensity. The speed of data collection can be of the order of 1 second per 1° rotation. In association with CCD detectors able to read out images within a few seconds, this means that a complete data set can be obtained in a few minutes. At first sight, this would seem to have solved the problem of macromolecular data collection, as such speeds should allow recording of highly redundant accurate data to the highest resolution in a tractable time.

However, with such high intensities it appears that the effects of radiation damage are significant and result in specific effects on susceptible parts of the structure. The useful active exposure lifetime of typical crystals seems to be around five minutes, with substantial degradation of the diffraction pattern ensuing even for vitrified crystals. The first manifestation of radiation damage is the disruption of disulfide bridges and decarboxylation of aspartates and glutamates. This effect means appropriate strategies for selecting the optimal starting point of rotation in order to minimize the total rotation required for collection of complete data are once more essential. Several strategy programs, such as *BEST* (Popov & Bourenkov, 2003; Bourenkov & Popov, 2006), now permit this to be done effectively.

9.1.12.4. Correcting data for the effects of radiation damage

The overall effect of radiation damage is that the higher-resolution intensities decrease faster than those at low resolution. This effect is largely taken into account by the relative *B* factors applied to individual images during data scaling and merging by the major data-reduction programs.

However, such scaling does not allow for the effect of specific structural damage (*e.g.* the S–S bridges and carboxylic groups) on individual reflection intensities. A method to deal with this has been proposed by Diederichs *et al.* (2003). This is based on a zero-dose extrapolation of intensities and requires that a timestamp be attached to each individual intensity measurement. Such a timestamp has also been used to assist in estimation of phases by *SHARP* (Schiltz *et al.*, 2004).

9.1.13. Relating data collection to the problem in hand

The data-collection protocol should be matched to the purposes for which the data are to be used. Different applications present a range of different needs, requiring the intensities (or structure-factor amplitudes) to be exploited in different ways. In this section a representative set of applications is outlined in terms of how the tactics and strategies of data collection can vary.

9.1.13.1. Isomorphous-anomalous derivatives

The phasing of proteins by isomorphous replacement requires the collection of data from crystals of one or more heavy-atom derivatives of the protein that are isomorphous to the parent native crystal. Preparation of derivatives involves either soaking of native crystals in the heavy-atom solution or co-crystallization with the heavy-atom reagent (Part 12). Data collection can be split into two parts. The first step is to establish whether a potential derivative is isomorphous and contains the expected heavy atoms. The second is to collect the data on this derivative to provide the necessary phase information for the native structure factors. The problems of how to utilize the phase information are addressed in Part 12. Here, strategies applicable to the two steps are described.

Screening of derivatives can be carried out by collecting data to the resolution limits of the crystals. This can consume substantial data-collection resources and lead to irrelevant data that are not from isomorphous crystals or do not contain the anticipated heavy-atom signal. It is preferable to record the minimum data sufficient to identify a potential derivative in order to save time and resources, as many samples may need to be screened. A minimal strategy can exploit some or all of the following protocols:

(1) An essentially complete native-data reference set should be available, although not necessarily to the ultimate resolution limit.

(2) Preparation of a set of crystals with a selected set of potential heavy atoms, the number depending on crystal availability.

(3) Collection of a small number of images from each potential derivative crystal, ideally on the home-laboratory rotating-anode source or an SR beamline if necessary. These data can be recorded to a low resolution: in principle 4 Å or less should be enough. The resulting partial derivative data are scaled with the complete native set. The fractional isomorphous difference can be evaluated easily and compared with the expected agreement with the native data. In general, values less than 10% suggest that the heavy atom is not bound. Values higher than about 30% suggest an unacceptable level of non-isomorphism. Intermediate values suggest, but do not guarantee, that the derivative is worth pursuing. Normal probability plots can be helpful in this respect (Howell & Smith, 1992).

(4) Given a positive result from point (3), complete data may be recorded on the same or an equivalent derivative crystal. Again, it may be useful to record data to low resolution in the first instance. 4 Å resolution is again quite sufficient to solve the structure of a heavy-atom constellation using direct or Patterson methods, allowing the more complete characterization of the potential derivative.

(5) If the compound proves to be a useful derivative, data can then be recorded to higher resolution for the computation of phase information. It may not be appropriate to record data to the highest resolution as for the native protein. In this context, the strength of the data is of primary importance, and relatively weak data at high resolution may be less relevant.

Some practical points are highly relevant here. The ability to store and reuse vitrified crystals means that potential derivatives can first be screened at the lowest possible resolution, and the crystal can be preserved and used later only if the derivative proves to provide useful phase information. The final resolution for data collection will then depend on the degree of isomorphism. The wavelength, if tunable, should be set to a value just below the absorption edge in order to maximize the anomalous signal. The redundancy can play an important role, as it is useful to have a large number of independent measurements so that outliers in the native or derivative data can be excluded, as these can cause major problems in either the Patterson or direct-methods approaches for locating the heavy atom (Part 12).

9.1.13.2. Anomalous scattering, MAD and SAD

The requirements for collecting data with an intrinsically weak anomalous signal are several. The highest possible resolution should not be the primary consideration. The emphasis is on data quality, as it is necessary to measure very small differences in structure-factor amplitudes, which are already in themselves relatively weak. Important considerations include the following.

(1) Optimization of the wavelength, particularly for MAD experiments.
(2) Ensuring that the anomalous data are complete in terms of all possible Bijvoet pairs. This is not always addressed by the currently available data-processing software.
(3) High redundancy of measurements significantly enhances the quality of the signal, as this provides effective averaging of errors and allows the rejection of statistical outliers. The latter is especially important for direct-methods solution of the anomalous-scattering constellation.
(4) However, the crystal lifetime is finite owing to the effects of radiation damage, which can introduce changes in intensities of the same order as the anomalous signal. For SAD (single-wavelength anomalous dispersion)/MAD data, the exposures should be limited to ensure the data are complete before the onset of substantial damage. This may well mean that the resolution limit should be set more modestly than for native data.

For MAD experiments (Hendrickson, 1999; Smith, 1991), which can only be carried out at SR sites, the optimum number of wavelengths at which data should be recorded remains unclear. Given finite beam time, the trade-off may be between measuring with limited redundancy at several wavelengths as against higher redundancy at a smaller number of wavelengths, or even at one wavelength.

SAD represents the limiting case. All data are recorded at one wavelength, reducing the requirement for fine monochromatization and for fine tunability and stability. Now quality, especially in the form of redundancy, is the dominating factor since all phasing is based purely on a single anomalous difference for each reflection. In recent years, SAD phasing has come to predominate in the number of novel structures deposited in the PDB.

9.1.13.3. Molecular replacement

For the initial data required for molecular replacement (MR), high resolution is not essential. Firstly, the method depends on homologous models that are usually only an imperfect representation of the structure under investigation, hence high-resolution data cannot be accurately modelled and will only introduce noise into the analysis. Secondly, the rotation function, the first step in MR, is based on the representation of the Patterson function in terms of spherical harmonics, which is limited in its accuracy.

In contrast, it is vital for MR applications that the most intense low-resolution terms are measured. The lack of such reflections strongly affects the rotation- and translation-function computations, as the functions are based on Patterson syntheses involving the square of the structure-factor amplitudes, and are dominated by the largest terms. Elimination of the strongest few per cent of the low-resolution data may well prevent a successful solution by MR.

However, for refinement of structures solved by MR, it is important that data be recorded to a resolution sufficient to allow escape from the phase bias introduced by the model. This is a key point. There are many examples where collection of data to a higher resolution has enabled the refinement of an MR solution which would not refine at the lower resolution.

9.1.13.4. Definitive data for refinement of protein models

All structures benefit from the highest accuracy in their atomic coordinates to shed light on the details of their biological function. These may include substrate or inhibitor complexes and mutants as well as native proteins where the analysis requires the full potential of X-ray crystallography. Many of these crystals will not diffract to atomic resolution; nevertheless, all steps in a detailed crystal structure analysis are made simpler as the resolution and quality of the data are increased. This includes solution of the phase problem, interpretation of the electron-density maps and refinement of the model.

The most appropriate strategy for data collection involves decisions based on a complex and mutually dependent set of parameters including:

(1) Crystal quality and availability. If only one crystal is available, the choices are limited. If many are available, then some experimentation is recommended to select a high-quality sample. This is greatly aided by the recent introduction of automated sample changers and strategy software on a number of beamlines.
(2) Cryogenic vitrification. In many cases, this allows collection of data from a single crystal. If appropriate cryogenic conditions cannot be established, making it necessary to record room-temperature data, this can affect strategy dramatically, in that several crystals might well be required to record the target resolution and completeness.
(3) X-ray source and detector. The availability of these again places restrictions on the experiments that are tractable. An SR source will always provide better data, but has logistical problems of availability and access. For some problems, SR becomes *sine qua non* and a rotating anode is just insufficient. These include the use of MAD techniques, very small crystals, large and complex structures with large unit cells such as viruses, and where atomic resolution data are needed.
(4) Overall data-collection time allocated. This has an obvious overlap with point (3). In particular, if SR is to be used later, then the resolution limit on the home source may be modest.

If SR is not likely to be employed, then a higher resolution may be aimed for, requiring more time, and again dependent on the pressure on local resources.

Whatever the resource, it is good to define a strategy that will provide high completeness of the unique amplitudes at the highest resolution, with the realization that there may be some conflict between these two requirements owing to radiation damage.

9.1.13.5. A series of mutant or complex structures

The detailed geometry of the molecule is already known and the rather general effects of ligand binding or mutation can be initially identified at a relatively modest resolution and completeness. As with heavy-atom screening, it is often advisable to check that the desired complex or structural modification has been achieved by first recording data at low resolution.

However, if the analysis then proves to be of real chemical interest, with a need for accurate definition of structural features, the data should be subsequently extended in resolution and quality. As with the identification of isomorphous derivatives, this approach has benefited greatly from cryogenic vitrification, where the sample can be screened at low resolution and then preserved for subsequent use.

9.1.13.6. Atomic resolution applications

As for MAD data, the needs for atomic resolution data are extreme, but rather different in nature. Atomic resolution refinement is addressed in Chapter 18.4. Suffice it to say that by atomic resolution it is meant that meaningful experimental data extend close to 1 Å resolution. There are two principal reasons for recording such data. Firstly, they allow the refinement of a full anisotropic atomic model, leading to a more complete description of subtle structural features. Secondly, direct methods of phasing are dependent upon the principle of atomicity.

The problems to be faced include:

(1) The high contrast in intensities between the low- and high-angle reflections. This may be much larger than the dynamic range of the detector. If exposure times are long enough to give good counting statistics at high resolution, then the low-resolution spots will be saturated. The solution is to use more than one pass with different effective exposure times.

(2) The overall exposure time is often considerable and substantial radiation damage may finally result. The completeness of the low-resolution data is crucial, and it is strongly recommended to collect the low-resolution pass first as the time taken for this is relatively small.

(3) The close spacing between adjacent spots within the lunes on the detector, dependent on the cell dimensions. The only aid is to use fine collimation.

(4) The overlap of adjacent lunes at high diffraction angle, especially if a long cell axis lies along the beam direction. Using an alternative mount of the crystal is the simplest solution. Otherwise, the rotation range per image must be reduced, increasing the number of exposures. This was a problem with slow read-out detectors, but is largely alleviated with CCDs.

(5) For direct-methods applications, a liberal judgement of resolution limit should be adopted. Even a small percentage of meaningful reflections in the outer shells can assist the phasing. These weak shells can be rejected or given appropriate low weights in the refinement. The strong, low-resolution terms are vital for direct methods.

9.1.14. The importance of low-resolution data

The low-resolution terms define the overall shape of the object irradiated in the diffraction experiment. Omission of the low-resolution reflections, especially those with high amplitude, considerably degrades the contrast between the major features of the object and its surroundings. For a macromolecule, this means that the contrast between it and the envelope of the disordered aqueous solvent is diminished and, furthermore, the continuity of structural features along the polymeric chain may be lost. Refinement and analysis of macromolecules at all resolutions, be they high or low, involves the inspection of electron-density syntheses. These can be interpreted visually, on a graphics station, or automatically with a variety of software. In all of these, at all resolutions, the importance of the low-resolution terms is crucial. A special problem is in the interpretation of the partially ordered solvent interface. The biological activity of most enzymes and ligand-binding proteins is located precisely at this interface, and for a true structural understanding of how they function this region should be optimally defined. This is seriously impaired by the absence of the strong, low-resolution terms. The problems become more severe as the upper resolution limit of the analysis becomes poorer. Thus, at 1 Å resolution the omission of the 7 Å data shell will have less effect compared with a 3 Å analysis – but remember that ideally, no low-resolution data should be omitted!

In some phasing procedures, the presence of complete, especially high-intensity, low-resolution, data is even more crucial. The big, low-resolution amplitudes dominate the Patterson function, and methods based on the Patterson function are therefore especially sensitive. This encompasses one of the major techniques of phase determination for macromolecules: molecular replacement. Direct methods of phase determination utilize normalized structure factors and predominantly exploit those of high amplitude. The relations between the phases of those reflections with high amplitudes, such as the classical triple-product relationship, are strongest and most abundant for reflections with low Miller indices, hence at low resolution.

The importance of the low-resolution reflections in terms of geometric and qualitative context cannot be overemphasized.

9.1.15. Data quality over the whole resolution range

It is not possible to judge data quality from a single global parameter, especially $R_{\rm merge}$, not even from the overall $I/\sigma(I)$ ratio. Such a parameter may totally neglect problems such as the omission of all low-resolution terms due to detector saturation. A set of key parameters including $I/\sigma(I)$, $R_{\rm merge}$, percentage completeness, redundancy of measurements and number of overloaded high-intensity measurements must be tabulated in a series of resolution shells. This information should be assessed during data collection to guide the experimenter in the optimization of the choice of such parameters as exposure time, attainable resolution and required redundancy. As stated in Section 9.1.13, the requirements will vary with the application.

The effect of sample decay also requires such tables. The X-ray intensities decay more rapidly at high angle than at low, and consideration of this effect requires knowledge of the relative B values that need to be applied to the individual images during data scaling. An often subjective decision will need to be made regarding at what stage the decay is sufficiently high that further images should be ignored. The effects of damage are likely to be systematic rather than just random, and cannot be totally compensated for by scaling. This remains true even for cryogenically vitrified crystals, especially with ultra-bright synchrotron sources.

Following an earlier recommendation by the IUCr Commission on Biological Molecules (Baker *et al.*, 1996), this tabulated information, as a function of resolution, should be deposited with the data and the final model coordinates in the Protein Data Bank. Only then is it possible to have a true record of the experiment and for users of the database to judge the correctness and information content of a structural analysis.

9.1.16. Strategies for automated data acquisition

Progress in crystal-handling hardware has resulted in the development of sample changers both for synchrotron beamlines and the home laboratory. A sequence of samples contained in a Dewar can be mounted on the goniostat, centred in the beam and exposed to X-rays without user intervention. The gain in efficiency arises from the fact that manual intervention is no longer needed between samples, and at SR sites access to the hutch is avoided.

While this provides the potential for greatly increased throughput, it still requires intelligent decision-making software for evaluation of crystals and for optimal strategies of data collection to be achieved with minimal (ideally zero) user input. The steps required in such a system are:

(1) Automated mounting and dismounting of samples from a Dewar.
(2) Automated centring of the sample (or at least loop) in the beam.
(3) Recording and interpretation of two images preferably 90° apart in crystal orientation.
(4) Repetition of steps (1)–(3) for a number of samples of the same protein and ranking of these samples in terms of diffraction quality.
(5) Selection of the best sample and definition of the optimum strategy for data collection, taking account of information provided by the user with regard to the minimum resolution *etc*.
(6) Collection and integration of complete and ideally redundant data.

Robotic sample changers with at least some elements of the above are now operational at many sites [for example, see Leslie *et al.* (2002); McPhillips *et al.* (2002) and Cipriani *et al.* (2006), and also Chapter 9.2]. Considerable advances are expected in the near future, allowing routine automated screening of samples at major synchrotrons. In addition, remote access to synchrotons, by submission of crystals in Dewars for collection by SR staff (the so-called Fedex procedures) or for direct control by the user from their home laboratory through the Internet, is now possible at a number of synchrotron facilities. All of these moves towards automation require electronic databases for the tracking and transfer of samples and their associated data and parameters.

9.1.17. Final remarks

Optimal strategies for data collection are dependent on a number of factors. The alternative data-collection facilities to which access is potentially available, how long it takes to gain access and the overall time allocated all place restraints on the planning of the experiment. In view of this, it is not possible to provide absolute rules for optimal strategies.

Even after the source and overall time have been allocated or planned, the strategy is still the result of a compromise between several competing requirements. Some are general, others depend on the characteristics of a particular crystal or detector. As seen in the previous section, it is not possible to define protocols relevant for all applications. Rather, it is important to consider the relative importance of the parameters that can be varied to the problem in question and make the appropriate decisions.

Thus, data collection may have become easier from a technical point of view, but several crucial scientific decisions still have to be made by the experimenter. It is always beneficial to sacrifice some beam time and interpret the initial diffraction images, so as to avoid mistakes which may have an adverse effect on data quality and the whole of the subsequent structural analysis.

Chapter 9.2. Robotic crystal loading

T. Earnest and C. Cork

9.2.1. Introduction

The three-dimensional structure of a biological molecule provides fundamental information about how it interacts with other molecules, co-factors and ligands that defines, at a molecular level, how the protein functions in the cellular environment. Protein structure information has also proved to be an invaluable tool in the development of new synthetically derived medicines. The determination of protein structures has significantly accelerated in the past decade, due in large part to advances in protein production (cloning, sequencing, expression and purification), protein crystallography (*e.g.* cryogenic freezing, intense synchrotron X-ray sources, area detectors) and computing. There has been an explosive growth in the use of synchrotron sources for the collection of X-ray diffraction intensities from protein crystals, since synchrotrons can provide bright tunable X-rays which are needed for both high-throughput projects and challenging biomolecular targets such as large complexes and membrane proteins (Wakatsuki & Earnest, 2000).

The convergence of a number of factors in the 1990s and early 2000s motivated the development of robotic crystal mounting – the increase in the number and performance of synchrotron beamlines for biological crystallography, improvements in detector speed, the motorization and computer control of beamlines, advances in computer hardware and software, and an increase in the demand for beam time as structural biologists began to pursue ever more difficult crystallographic projects. Structural genomics efforts and structure-based drug-design programmes benefited significantly, with an increase in the throughput of data collection and analysis for which these systems provided an enabling technology. During the 1990s, the use of cryogenic data collection, instead of mounting in glass capillaries, also allowed synchrotron beamlines to be used more productively, since the bright beams lead very rapidly to the onset of radiation damage unless the crystal is preserved and maintained at low temperatures, typically ~100–120 K.

9.2.2. Robotic sample loaders

Significant amounts of synchrotron beam time can be lost due to crystal manipulation and misalignment by the beamline user, which becomes more critical with the increase in brightness and stability of the newer synchrotron sources. Crystal-screening and data-collection runs have become significantly shorter. Therefore, more efficient mounting and alignment tools have been developed that reduce the fraction of time spent changing samples, including the implementation of robotic sample loaders (automounters), which can greatly facilitate the throughput and production of crystallography beamlines and other X-ray sources.

There are several benefits to using an automounter system, particularly on bright synchrotron beamlines:

(i) *It facilitates optimum use of synchrotron beam time.* Crystallography experiments are installed in radiation-shielded hutches, which are inaccessible during data collection. Changing the crystal manually requires opening and closing the hutch, initiating the interlocks and performing a hutch search, which typically takes several minutes. The automounter significantly reduces both the sample mounting time and the number of required hutch accesses.

(ii) *It facilitates advanced data-collection techniques.* An experimental station can be fully automated, including integrated data collection and processing whereby the structure-solving software can influence the data-collection process (*e.g.* crystal ranking and data-collection strategy determination). Remote data collection, where the researchers send cryoprotected crystals (maintained near liquid-nitrogen temperatures) to the beamline for robotic mounting and automated (or semi-automated) data collection, can proceed in a flexibly scheduled manner.

(iii) *It facilitates the collection of higher-quality data.* The rapid crystal-interchange mechanism enables the researcher to evaluate a large pool of samples and to select the best crystals from the set.

(iv) *It reduces risk to crystals.* Automated mounting and dismounting of crystals can be done much more reliably than manual handling.

(v) *It facilitates systematic studies of experimental protocols.* Alternative protocols can be performed in a manner and number that would be impractical for humans to perform manually. Furthermore, this can allow for an intelligent system to 'learn' improved methods of data collection and processing.

The major challenge in the design of automation hardware for the mounting and alignment of crystals of biological samples is the necessity to maintain the sample at approximately 100 K, since cryogenic data collection is required at synchrotron beamlines and usually at home sources as well. The process involves the optical screening of several candidate crystals under a microscope, followed by 'freezing' the selected crystal in an amorphous glass formed by the mixing of reservoir and cryoprotectant solutions. In this manner, it is possible to manipulate small or fragile crystals more easily. More importantly, the frozen crystals are far more resistant to X-ray induced radiation damage, a common problem at synchrotron sources. The frozen crystals can then be stored indefinitely in liquid nitrogen and handled with minimum difficulty at cryogenic temperatures. There are established procedures for the manual manipulation and mounting of the crystal while at cryogenic temperatures. At the beamline, the crystals are transferred from the transport container to a small holding Dewar. Next, they are mounted in a secondary sample-transfer tool, and then they are transferred to the X-ray diffractometer. These can be very time-consuming steps when performed manually. Consequently, instrumentation has been developed to minimize the extent of manual manipulations of frozen crystals at the beamline (Snell *et al.*, 2004; Cork *et al.*, 2006) (Fig. 9.2.2.1). Groups at Abbott (Muchmore *et al.*, 2000), at the SSRL (Cohen *et al.*, 2002), at European facilities (Cipriani *et al.*, 2006) and in Japan (Ueno *et al.*, 2006) have similarly produced robotic crystal-mounting systems with a diversity of approaches to achieve the same goal. systems have also been developed (*e.g.* the Rigaku ACTOR and the IRELEC CATS).

There are two basic approaches that have been pursued: (i) the use of commercial multi-axis robots (Muchmore *et al.*, 2000; Cohen *et al.*, 2002; Rigaku ACTOR) and (ii) modular purpose-built systems, such as the one developed at the Lawrence Berkeley Laboratory Advanced Light Source and shown in Fig. 9.2.2.1(*b*) (Snell *et al.*, 2004). All systems must take into consideration that the procedures used to transfer samples from a crystal tray and mount them on the goniometer need to ensure that the crystals be maintained in a frozen frost-free environment and transferred rapidly. For example, the system developed at the Advanced Light Source can be adapted for use with a variety of experimental station configurations. The only significant constraint in the use of this design is that the nitrogen cold stream subsystem must be oriented off-axis from the primary goniometer axis. The first automounter was installed on experimental station BL5.0.3 at the Advanced Light Source, a fixed wavelength station with significant access constraints. This system has been in operation since March 2001. Shortly thereafter, systems were installed on a second monochromatic experimental station, BL5.0.1, and also on a multiwavelength experimental station, BL5.0.2 (Snell *et al.*, 2004). The automounter configuration is essentially identical for all three experimental stations with a high degree of standardization. The sample-mounting robot consists of three main components: the gripper, which holds the sample during transport from the Dewar to the goniometer while keeping it at low temperature and frost-free; the X–Y–θ stage, which performs the actual transport; and the Dewar stage, which supports the samples in a regular array submerged in liquid nitrogen and positions the selected sample for access by the transporter (Fig. 9.2.2.1*b*).

The gripper contains a conically shaped brass collet that can be opened and closed using a small pneumatic actuator (Fig. 9.2.2.2). The collet is precooled to ~100 K before engaging the sample holder. A sensor inside the collet is used to monitor its temperature. The inner tube is surrounded by a low thermal capacity outer shroud (a very thin stainless steel tube), which provides a sheath flow of warm dry gas to reduce icing and frost formation during exposure to ambient moisture-laden air. During continuous use, ice is periodically removed from the gripper by means of an air-jet heater (*cf.* Fig 9.2.2.1*b*). Additionally, the gripper has a small low-force linear stage (labelled 'small move' in Fig. 9.2.2.2). This stage is used for the final positioning of the gripper on the sample during mounting and dismounting. The sample gripper was originally designed around the standard Hampton metal cap, which is held on the goniometer by a permanent magnet. A modified cap design, which has tighter tolerances and a conical shape rather than a ledge, has been

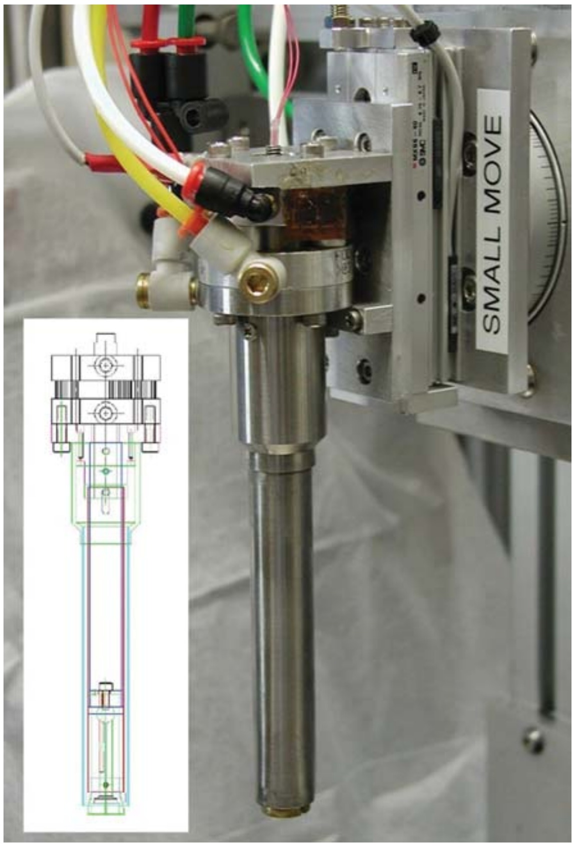

Figure 9.2.2.2
Crystal gripper assembly with low-force actuator (labelled 'small move').

designed to increase automounter reliability (also available from Hampton Research as part No. HR4-779).

The gripper is mounted on a pneumatic X–Y–θ stage, which is used to transport samples between the goniometer and the storage Dewar. A vertical Y stage moves the gripper in and out of the Dewar, a 90° rotational θ stage orients the gripper either horizontally or vertically, and a long horizontal X stage moves the gripper between the Dewar and the goniometer mount points.

When they are not mounted on the goniometer for data collection, the samples are maintained in a small cylindrical Dewar (see Fig. 9.2.2.1*b*). A custom cassette or puck (Fig. 9.2.2.1*a*) facilitates automated handling and bulk transport. Up to seven cassettes (112 samples) can be loaded into the sample Dewar. The Dewar is mounted on an R–θ motorized stage, which is used to position the selected sample for access by the gripper. The Dewar can also be positioned such that the gripper will be inserted into an unoccupied space for a precooling action when boiling of liquid nitrogen might endanger the samples. The Dewar is automatically filled directly from the facility's liquid-nitrogen supply system. During normal operations, an insulated and heated cover reduces icing and evaporation of liquid nitrogen. The gripper reaches into the Dewar through a small heated hole in the cover. The sample cassettes are moved in or out of the Dewar through a small access port in the cover.

The Robosync web site (http://smb.slac.stanford.edu/robosync/), maintained by the SSRL Structural Molecular Biology Group, features a list of biological crystallography beamlines with automated crystal mounting systems.

Important for the efficient and productive use of robotic crystal mounters is their integration into the beamline control system (McPhillips *et al.*, 2002; Snell *et al.*, 2004). The different motions of the automounter can typically be actuated from a software interface, either individually or through scripts which run a sequence of actions. The development of more fully automated capabilities requires the integration of the automounter and beamline control system with the data collection and analysis software. To this end, software has been developed that provides a framework for indexing integration and symmetry determination, along with suggested strategies for data collection (González *et al.*, 2008). When coupled with bright synchrotron beamlines and automounters, the underlying requirements for building fully automated and optimized data collection are mostly in place. The development of intelligent automated control (through *e.g.* artificial-intelligence approaches) should permit fully automated data-collection facilities to collect optimized data from a wide range of structural projects in the most efficient and cost-effective way and with minimal human intervention prior to the scientific analysis of the structures obtained.

9.2.3. Conclusion

In summary, the development of automounters over the past decade has been driven by the demands of greater access to synchrotron resources, the need for high-throughput data collection from projects that require numerous structures (*e.g.* structure-based drug-design and structural genomics programmes) and the demonstrated improvement in data quality for more challenging projects (such as large complexes and membrane proteins) that require the screening of numerous crystals in order to select those with the best diffraction characteristics. A number of different designs have been implemented at synchrotron sources worldwide, to the significant advantage of the structural biology community.

The authors thank their collaborators at the LBNL Engineering Division, the Berkeley Center for Structural Biology, the Advanced Photon Source, the National Synchrotron Light Source and the Cornell High Energy Synchrotron Source, as well as the numerous users who provided valuable testing and comments. We also thank the National Institute of General Medical Sciences of the National Institutes of Health for generous long-term support for this scientific engineering project.

Chapter 9.3. X-ray diffraction imaging of whole cells

D. Shapiro

9.3.1. Introduction

The brightness of third-generation synchrotron X-ray sources removes the need to enhance a diffracted X-ray signal with crystallographic redundancy for certain classes of samples. This is particularly useful for samples for which there exists only one unique structure or for which arrangement into a crystalline form is exceedingly difficult. Single-particle X-ray diffraction microscopy, also known as coherent X-ray diffraction microscopy (CXDM), treats an isolated non-crystalline sample as a crystallographer treats a crystal. The far-field diffraction intensity pattern of the sample is measured and the phase problem is solved computationally, allowing for structure recovery through a Fourier transform. Since Mother Nature restricts us to only measuring intensities, all methods of phase retrieval rely on decoding phase information that has been encoded in intensity measurements. Crystallographers, and the subsequent diffraction microscopists, have two basic methods for doing this. The first, the holographic method, mixes a known reference signal with the desired and unknown signal. The coherent superposition of these two signals results in measureable intensity variations that are directly related to the relative phase. This is, indirectly, a phase-measuring method. The second method relies only on the signal from the unknown structure and additional information, supplied by the scientist, which is physically plausible. This is a constraint-based method. Both methods seek to fill the information deficit inherent in intensity measurements by adding something that may unlock the phase.

In 1980, David Sayre suggested that CXDM should be possible (Sayre, 1980). Algorithms being developed for electron microscopy in the early 1970s would establish the constraint-based paradigm of iterative phase retrieval from Fourier modulus measurements. In particular, the alternating projection algorithm of Gerchberg and Saxton, the error-reduction algorithm, was developed to reconstruct the phase information that is missing when intensity measurements are made in both real and reciprocal space (Gerchberg & Saxton, 1972). This algorithm was later modified by Fienup into the input–output algorithm to handle cases where only one intensity measurement is made (Fienup, 1978, 1982; Fienup *et al.*, 1982; Miao *et al.*, 1998). In this case, the required real-space constraint restricts the object to an area no larger than half the width of its autocorrelation. The combination of the input–output algorithm and the error-reduction algorithm was found to be a very robust method of image reconstruction using only Fourier domain intensities, but its success was not understood for several years. In 1982, Bates argued that the solutions to the phase problem are unique in two dimensions if the Fourier modulus is sampled on an interval at least twice as fine as the Bragg interval (Bates & Fright, 1983; Bates, 1982). The method of phase retrieval from diffraction patterns sampled between Bragg peaks became known as the oversampling phasing method (Sayre, 1991; Sayre & Chapman, 1995; Miao *et al.*, 1998). The oversampling method compensates for the information deficit by supplying a zero-density region of approximately known size in the object domain. The more finely the diffraction pattern is sampled, the larger this zero-density region is, although this only adds useful information up to a certain point. This addition of information through Fourier space sampling results in an overdetermined inverse problem with a unique solution.

Sayre considered that the real niche of CXDM would be imaging objects of a few microns at a resolution of a few nanometres using soft X-rays (1–10 nm wavelength). Indeed, since the initial demonstration of CXDM (Fig. 9.3.1.1), ten years ago at the time of writing, active research projects have developed at all major synchrotron facilities and the technique has been applied to a diverse set of scientific problems. Three-dimensional images of radiation-hard materials have been obtained at 15 nm resolution, while two-dimensional images of a whole cell at 30 nm and of a gold nanoparticle at 5 nm resolutions have been reported, among many others (Miao *et al.*, 2002; Shapiro *et al.*, 2005; Pfeifer *et al.*, 2006; Barty *et al.*, 2008; Schroer *et al.*, 2008; Nelson *et al.*, 2010). CXDM researchers have not yet achieved the 'holy grail' of cellular imaging, the imaging of a whole frozen hydrated cell in three dimensions, but at least two teams are pursuing this goal with recent success in the two-dimensional case (Huang *et al.*, 2009; Lima *et al.*, 2009). Lens-based X-ray microscopes have achieved this landmark with moderate resolution (Wang *et al.*, 2000; Weiss *et al.*, 2000; Larabell & Le Gros, 2004). Transmission X-ray microscopes (TXM) and scanning transmission X-ray microscopes (STXM) utilizing diffractive zone plate lenses have high throughput and the advantage of direct imaging, but are limited in resolution by the technological challenge of making efficient high-numerical-aperture lenses. TXM can now routinely image in three dimensions at 50 nm resolution, and 12 nm resolution has

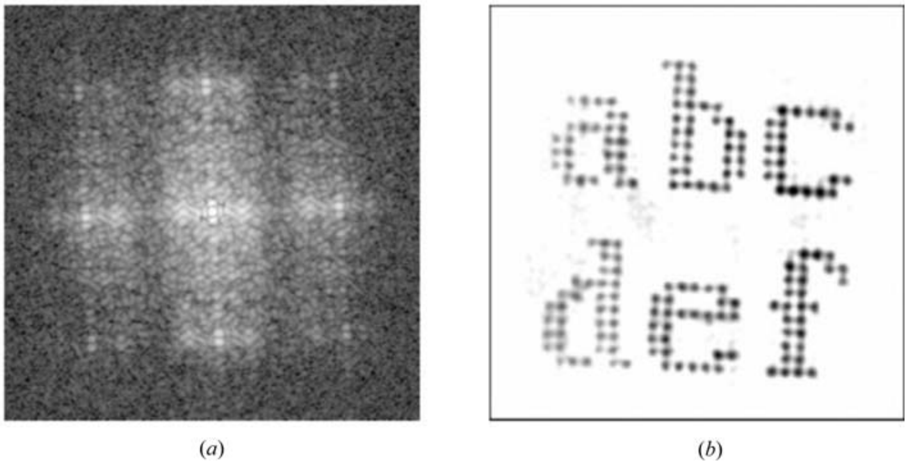

Figure 9.3.1.1

been demonstrated in two dimensions, although the total efficiency of the optic used was of the order of 1% (Chao *et al.*, 2009) at the highest spatial frequencies. Thus, at the cost of throughput and ease of use, a diffraction microscope provides increased X-ray efficiency and resolution.

Table 9.3.2.1
Summary of various algorithms

The algorithms are, from top to bottom: error reduction, solvent flipping, hybrid input–output, difference map, averaged successive reflections, hybrid projection–reflection and relaxed averaged alternating reflections. A reflection is defined by its associated projection as $\mathbf{R} = 2\mathbf{P} - \mathbf{I}$, where $\mathbf{I}$ is the identity projection (Marchesini, 2007).

Algorithm	Iteration $\rho^{(n+1)} =$
ER	$\boldsymbol{P}_s\boldsymbol{P}_m\rho^{(n)}$
SF	$\boldsymbol{R}_s\boldsymbol{P}_m\rho^{(n)}$
HIO	$\begin{cases} \boldsymbol{P}_m\rho^{(n)}(\boldsymbol{r}), & \boldsymbol{r} \in S \\ (\boldsymbol{I} - \beta\boldsymbol{P}_m)\rho^{(n)}(\boldsymbol{r}), & \boldsymbol{r} \notin S \end{cases}$
DM	$\{\boldsymbol{I} + \beta\boldsymbol{P}_s[(1+\gamma_s)\boldsymbol{P}_m - \gamma_s\boldsymbol{I}]$ $-\beta\boldsymbol{P}_m[(1+\gamma_m)\boldsymbol{P}_s - \gamma_m\boldsymbol{I}]\}\rho^{(n)}$
ASR	$(1/2)[\boldsymbol{R}_s\boldsymbol{R}_m + \boldsymbol{I}]\rho^{(n)}$
HPR	$(1/2)\{\boldsymbol{R}_s[\boldsymbol{R}_m + (\beta - 1)\boldsymbol{P}_m] + \boldsymbol{I} + (1-\beta)\boldsymbol{P}_m\}\rho^{(n)}$
RAAR	$[(1/2)\beta(\boldsymbol{R}_s\boldsymbol{R}_m + \boldsymbol{I}) + (1-\beta)\boldsymbol{P}_m]\rho^{(n)}$

The following sections first report on the current standard single-particle phase retrieval techniques and then on recent experiments in CXDM, which establish the state of the art in whole-cell imaging by diffractive methods. Images of dry yeast at 11 nm resolution are presented, which represent the highest resolution X-ray images of whole cells currently on record. The effects of radiation damage are discussed and Sayre's idea of using stereoscopic viewing as a means of obtaining quick and low-dose three-dimensional information is explored (Sayre, 2008).

9.3.2. Phase retrieval from single-particle diffraction data

The problem of phase retrieval is solved through successive application of constraints on the recovered object in the data and object spaces. Using the language of convex optimization, the mathematical operators which act on the data are projectors. The projector in the reciprocal (data) space forces the Fourier components to have the correct magnitude, while in object space finite support is enforced. To calculate the Fourier magnitude projector, one first needs to propagate the object density, ρ, to the data space by a Fourier transform, then replace the estimated magnitudes $|\tilde{\rho}|$ with the measured ones, $I^{1/2}$, and finally propagate back to real space. Using these transforms one simplifies the calculation of the projection, which becomes an element-wise operation on each recovered Fourier component. The forward $\mathcal{F}$ and inverse $\mathcal{F}^{-1}$ transforms must be incorporated into the operator defined in real space $\mathbf{P}_m$,

$$\mathbf{P}_m = \mathcal{F}^{-1}\tilde{\mathbf{P}}_m\mathcal{F}, \qquad (9.3.2.1)$$

where the measured Fourier magnitudes are enforced in Fourier space by $\tilde{\mathbf{P}}_m$. Using the Fourier basis, one simply replaces the estimated magnitudes $|\tilde{\rho}|$ with the measured ones $I^{1/2}$, $[\tilde{\mathbf{P}}_m\tilde{\rho}(\boldsymbol{k}) = I(\boldsymbol{k})^{1/2}\tilde{\rho}(\boldsymbol{k})/|\tilde{\rho}(\boldsymbol{k})|]$. Similarly, in the object space the finite support constraint is applied on a per pixel basis through multiplication by the support mask. The corresponding projector is

$$\mathbf{P}_s\rho = S \cdot \rho.$$

Table 9.3.2.1 lists the combination of projections used by the most popular algorithms.

The violation of the support constraint is used as an error metric to monitor the convergence towards the solution. The solution should have zero density outside the support mask, so the error can be defined as the total density outside the support area,

$$\varepsilon_s^2(\rho) = |||\rho - S\rho|||^2 = ||[I - \mathbf{P}_s]\rho||^2. \qquad (9.3.2.2)$$

Alternatively, the error metric can be defined in the data space as the difference between the measured and calculated magnitudes,

$$\varepsilon_m^2(\rho) = |||\mathcal{F}\rho| - I^{1/2}||^2 = ||[I - \mathbf{P}_m]\rho||^2. \qquad (9.3.2.3)$$

In reality, the measured intensities are subject to noise which prohibits exact compliance with the constraints, so the error metrics cannot drop to zero. Although in most cases the algorithm can locate the global minimum, random noise will force fluctuations around the minimum. Once the algorithm reaches this steady-state regime, any particular iterate chosen as the solution would have a misleading degree of detail. On the other hand, the average of many fluctuating iterates would have reduced intensity in those Fourier components which are not reliably phased. The ratio of the average Fourier magnitude to the measured magnitude provides a measure of the stability, or reproducibility, of the retrieved phase information. This ratio as a function of spatial frequency is the phase retrieval transfer function (PRTF),

$$\mathrm{PRTF}(\mathbf{q}) = \frac{|\mathcal{F}[\langle\psi\rangle]|(\mathbf{q})}{[I_m(\mathbf{q})]^{1/2}}, \qquad (9.3.2.4)$$

where $\mathcal{F}[\langle\psi\rangle]$ is the Fourier transform of the final averaged image and I_m is the measured intensity pattern. The PRTF is analogous to the differential phase residual of electron microscopy and, following Chapman *et al.* (2006), the resolution of a reconstruction is chosen as the spatial frequency at which the PRTF falls below a value of 0.5.

9.3.3. High-resolution imaging of yeast

The X-ray dose required to image a given volume of protein is nearly independent of energy above the oxygen K edge. At the same time, the photon flux required to image the same volume increases with E^2 because of the energy dependence of the scattering cross section (Howells *et al.*, 2009). For this reason, it is advantageous to use the lowest energy commensurate with the desired resolution of 5–10 nm. Commercially available charge-coupled device (CCD) detectors can easily provide a scattering angle of 0.1 radians [a 1 inch detector placed 5 inches from the sample (1 inch = 2.54 cm)], which results in a half-period resolution of 8 nm when using 750 eV X-rays. Furthermore, a cell with a diameter of 3 µm would have an oversampling ratio (number of intensity samples per speckle) of at least ten in this geometry if the detector has 20 µm pixels.

In this particular case, a Princeton Instruments CCD (PI-MTE:1300) is placed 136 mm downstream of a freeze-dried yeast cell using the CXDM instrument on Beamline 9.0.1 of the Advanced Light Source (ALS). The yeast cell is illuminated by a coherent beam of 750 eV X-rays defined by a 5 µm pinhole located 25 mm upstream. The incident intensity of 4×10^6 photons s^{-1} µm^{-2} is high enough to cause rapid structural changes to the cell (discussed in the next section), so the sample requires pre-irradiation for about 30 minutes prior to collection of the final data set intended for reconstruction. The final data set, shown in Fig. 9.3.3.1, is a 1024 × 1024 pixel subset of the full CCD and extends to a resolution of 11 nm at the edge and 7.8 nm in the corner. Speckles extend to the corner of the data set after a total exposure of 406 s and to the edge after 226 s.

The full reconstruction of this type of data set can only proceed once a high-fidelity support is determined. Algorithmic support determination using *Shrinkwrap*, a variation on the hybrid input–output algorithm, is straightforward for objects with sharp boundaries, as is often the case in the material sciences (Marchesini *et al.*, 2003; Chapman *et al.*, 2006). However, biological samples which often have soft boundaries require manual intervention in the early stages of reconstruction. The soft-edge problem is exacerbated by the loss of low spatial frequency information behind the beamstop. A combination of *Shrinkwrap* support adjustments and intuitively reasonable manual adjustments are made until the algorithm is stable to automatic adjustment. This point is found when further *Shrinkwrap* adjustments no longer alter the shape of the support but just its tightness. High-fidelity reconstructions of complex-valued objects are not possible with a loose support (Fienup, 1987). Once the support is found, the final image is produced as the average over many reconstructions, all using the same support, which are started from different random phase sets. This averaging procedure, discussed earlier, reduces features that are primarily due to noise and provides a measure of the reproducibility of the recovered phases and therefore an estimate of the resolution. The final reconstruction shown in Fig. 9.3.3.1 had PRTF values above 0.5 for spatial frequencies extending to the edge of the data set or 11 nm resolution. The inset image clearly shows features of the order of 15 nm in size. In general, it is not possible to identify cell organelles without labelling specific proteins. However, a correlative study of yeast which combines high-resolution CXDM with optical fluorescence would be a powerful tool for the cell-biology community. This technique has already been demonstrated at lower resolutions using a transmission X-ray microscope (Le Gros *et al.*, 2009).

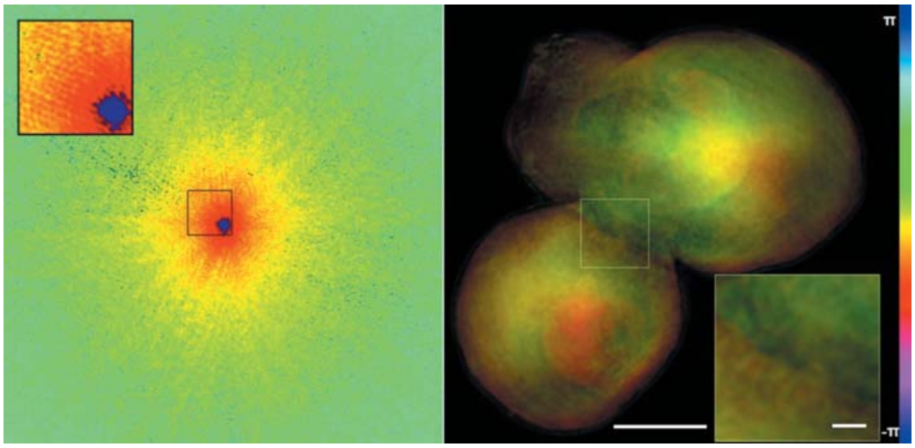

Figure 9.3.3.1
Diffraction pattern (left) and reconstruction (right) of a freeze-dried budding yeast cell. The diffraction pattern, measured on Beamline 9.0.1 of the ALS, extends to a half-period resolution of 11 nm and required 226 s of X-ray exposure. The blue regions of the diffraction pattern represent zeroes (noisy measurements or pixels lost behind the beamstop) and were left unconstrained during phase retrieval. The image represents the complex-valued X-ray wavefield after passing completely through the scattering potential, but propagated to the interior plane with the smallest support. The X-ray phase is represented as image hue and magnitude as brightness. The PRTF (not shown) never dips below 0.5, indicating that the magnitudes were adequately phased to the corner of the recorded data. The large scale bar is 1 µm, while the inset scale bar is 100 nm. The reconstruction presented here is the average of 25 independent reconstructions, each starting with a different set of random phases. Each reconstruction required 2000 iterations of the hybrid input–output algorithm and took about 14 s to complete on an nVidia Tesla C1060 graphics processing unit.

9.3.3.1. Radiation damage

High-resolution imaging of single particles with X-rays requires a large radiation dose because of the very strong dependence of the scattering cross section on spatial frequency and because, in the single-particle case, there is none of the coherent amplification one obtains when many identical copies of the particle are arranged into a crystal. This large dose means that either the sample must be protected from morphological changes induced by radiation exposure, most effectively through cryogenic techniques, or that the obtained images will represent an altered form of the original sample. Cryoprotection of hydrated cells has been successfully used in electron microscopy and lens-based X-ray microscopy for some time, but the sample preparation requirements of diffractive imaging are more severe, so the development of cryotechniques has been slower. The requirements of a finite sample support and that the sample be maintained on a zero-scattering background are extraordinarily difficult to achieve when that background consists of a micron-thick layer of ice. This is an active area of research by several X-ray diffraction microscopy groups.

For the case of dry cells, various preparation techniques (freeze drying or chemical fixation and dehydration) can preserve the large-scale internal structure, such as the size and shape of large organelles, but the ultrastructure will inevitably show artifacts of the drying process. Furthermore, exposure to ionizing radiation results in the well known shrinkage problem. Studies with a transmission X-ray microscope indicate that X-ray induced shrinkage primarily produces a higher-density but smaller version of the original cell (Jearanaikoon & Abraham-Peskir, 2005). The effect of cell shrinkage on the X-ray diffraction pattern is shown in Fig. 9.3.3.2. A freeze-dried cell is repeatedly exposed to 750 eV X-rays from Beamline 9.0.1 of the ALS. Each exposure is 30 s and delivers an X-ray dose of approximately 5 × 10^8 Gy. The sample is stable for the first two exposures but then experiences a rapid collapse, followed by a slow but continuous shrinkage. The collapse is apparent from the elongated speckles, which indicate a sample for which the diameter is changing during the exposure while its relative structure is maintained. Overall, the sample loses about 25% of its volume prior to the final exposure used for reconstruction (Shapiro *et al.*, 2005; Thibault *et al.*, 2006). Over the course of this exposure series the total scattered signal does not change, indicating that the total mass of the sample remains intact. The rapid change in the diffraction pattern during the early exposures means that successful imaging experiments require pre-irradiation of the sample. The slow but continuous shrinkage of dry samples with further dose means that the resolution of the three-dimensional images will necessarily be reduced. Indeed, Nishino *et al.* (2009) observed reduced resolution in their three-dimensional reconstruction of a dry chromosome because of morphological changes which occurred during data collection. Hence, full three-dimensional imaging of cells by diffractive methods requires cryogenic protection against radiation damage. Predictions based on a calculation of the cross section for coherent scattering by a smooth dielectric indicate that 10 nm resolution imaging of frozen hydrated organic matter should be possible using soft X-rays at currently available synchrotron sources (Howells *et al.*, 2009). This limit is arrived at through a comparison of the radiation dose required for imaging and the dose at which radiation damage has been empirically observed at different length scales. However, it seems plausible that the presence of many identical particles within a cell could be exploited to provide super-resolution information.

9.3.3.2. Low-dose three-dimensional imaging; low damage potential of stereoscopic viewing

Diffraction imaging in three dimensions proceeds as it does in standard X-ray tomography. That is, two-dimensional data are recorded from many angular orientations of the sample and then assembled into a three-dimensional data set. In this case, however, the data are recorded in reciprocal space and the individual data sets only need to be registered with respect to the angular coordinate due to the Fourier shift theorem. In the absence of any additional information, the angular sampling of reciprocal space is determined by the Crowther resolution,

$$k_C = \frac{1}{\Delta\theta D},$$

where D is the object diameter and $\Delta\theta$ is the angular separation of the two-dimensional data sets. This is the spatial frequency at which the unmeasured Fourier components, those in between the measured Ewald sphere segments, can be properly interpolated from the measured data. Diffraction microscopy, however, requires the addition of information in the form of real-space constraints. This additional information allows for the calculation of not only the missing reciprocal-space phases but also a limited number of missing magnitudes. Chapman *et al.* (2006) showed that $\Delta\theta$ could in fact be up to four times larger than required by the Crowther relation, with k_C matching the numerical aperture of the imaging system. Thus, three-dimensional reconstructions could take place with nearly isotropic diffraction-limited resolution with only about 150 angular orientations of the sample.

Stereoscopic viewing can provide a significant degree of three-dimensional perception of an extended object while only increasing the total radiation exposure by a factor of two. In principle, according to the dose-fractionation theorem of Hegerl and Hoppe, full three-dimensional visualization of a given resolution element should not require a dose any higher than two-dimensional visualization of the same element with the same statistical accuracy (Hegerl & Hoppe, 1976). This theorem provides hope that high-resolution imaging in three-dimensions, perhaps even of dry specimens, is possible, but in practice this is very difficult to achieve and low-dose imaging techniques are only now being explored by the CXDM community. Stereoscopic viewing should be considered the preliminary low-dose technique of choice. One particular advantage is the rapid reconstruction (compared with full three-dimensional reconstructions) which makes possible *in situ* sample inspection. Fig. 9.3.3.3 shows a stereo image of a chemically dried budding yeast cell. When viewed stereoscopically, with the viewer's focus in front of the image, the three-dimensional arrangement of a group of vesicles in the mother cell can be visualized.

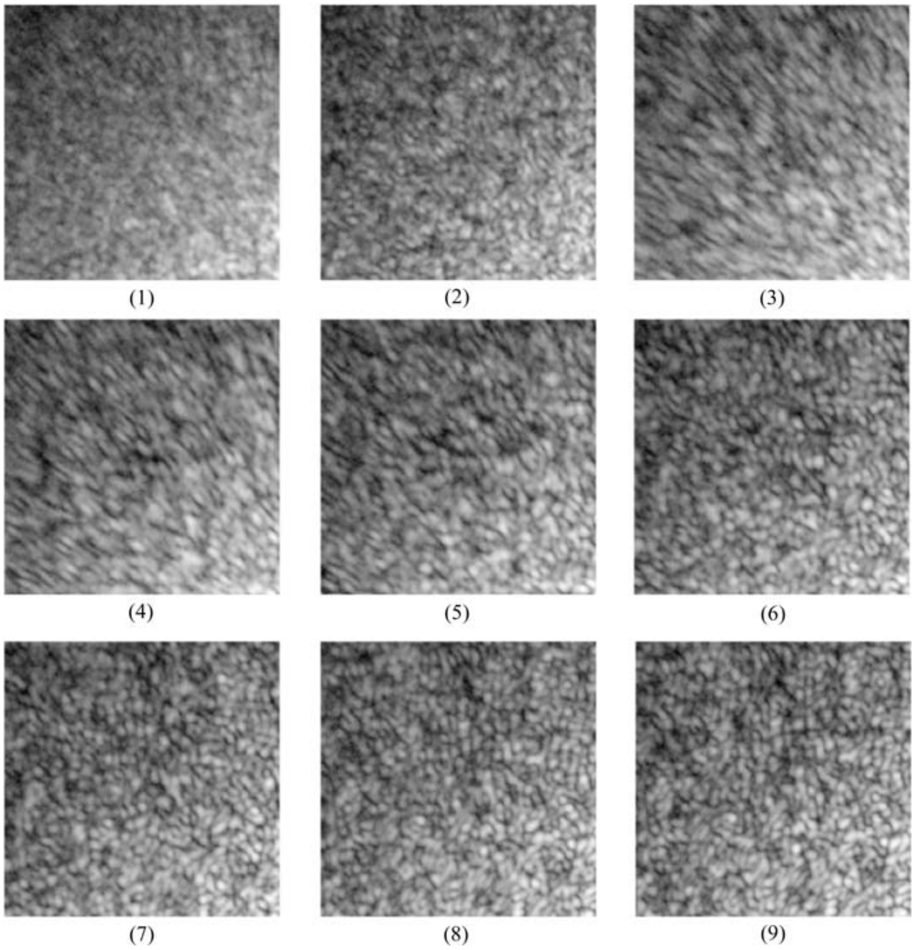

Figure 9.3.3.2
Exposure to ionizing radiation causes shrinkage of organic matter. Each image in this series is a section of a measured diffraction pattern from a freeze-dried yeast cell. The images were taken sequentially and each represents an additional X-ray dose of 5×10^8 Gy. After a cumulative dose of 1×10^9 Gy, the cell undergoes a rapid collapse [apparent from the elongated speckles in images (3)–(5)] followed by continued shrinkage at a reduced rate. The X-rays used had an energy of 750 eV and a dose of 5×10^8 Gy was adequate for reconstruction at 30 nm resolution. (Reproduced from Shapiro, 2004).

9.3.4. Conclusions

CXDM promises to be a highly efficient imaging methodology which can deliver high-resolution and high-contrast images of large non-crystalline biological structures. Radiation-induced shrinkage of dry cells will probably prohibit three-dimensional imaging of such cells at high resolution. However, significant three-dimensionality can be achieved through stereoscopic viewing of a cell, which only doubles the necessary X-ray dose. Even so, in the absence of low-dose diffraction techniques the sample must undergo considerable morphological change prior

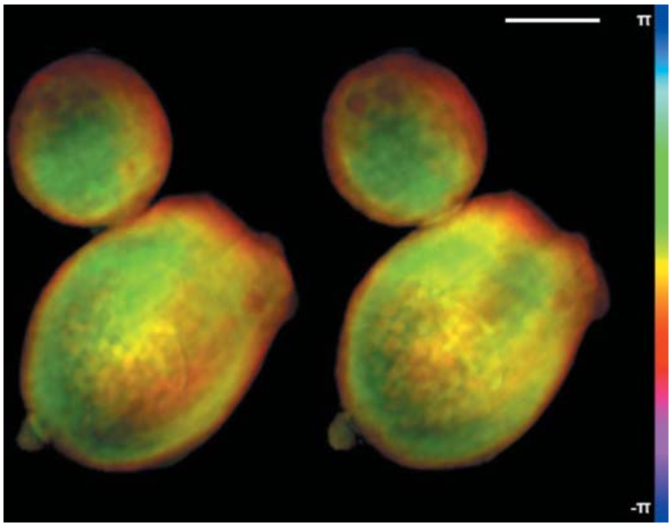

Figure 9.3.3.3
Stereo image of a budding yeast cell. This budding yeast cell was chemically fixed with gluteraldehyde and dehydrated in acetone. The images have an angular separation of 10° and a pixel size of 11 nm. The three-dimensional arrangement of a group of small vesicles in the mother cell can be visualized when viewed stereoscopically (with the viewer's focus in front of the image). The scale bar is 500 nm.

to imaging, although this change does not seem to alter the relative arrangement of organelles. The development of low-dose techniques will allow for the direct observation of these radiation-induced changes. In the long run, it is cryogenic protection that provides the most valuable structural information, since the cells are maintained in a near living state. Ultra-high-resolution three-dimensional imaging will still require the development of low-dose techniques, as cryoprotected samples have also been observed to suffer from mass loss with the accumulation of very high X-ray doses ($>10^{10}$ Gy). These imaging techniques are currently under development at the ALS in collaboration with Stony Brook University and elsewhere. Alternatively, X-ray free-electron lasers (FELs) promise the highest resolution imaging of living cells that is possible by any means; indeed, it has been proposed that sub-nanometre resolution is possible (Bergh *et al.*, 2008). The ultra-short and ultra-bright pulses of an X-ray FEL will encode the structural information from a living cell before it is destroyed by the pulse.

The author would like to thank Johanna Nelson and Xiaojing Huang of Stony Brook University for preparing the samples and providing the diffraction data for reconstruction. This work was supported under the Seaborg Fellowship at Lawrence Berkeley National Laboratory and by grants from the National Institutes of Health, the National Science Foundation and the US Department of Energy to Stony Brook University. The Advanced Light Source at Lawrence Berkeley National Laboratory is supported by the Director, Office of Science, Office of Basic Energy Sciences, Materials Sciences Division, of the US Department of Energy.

PART 10. CRYOCRYSTALLOGRAPHY

Chapter 10.1. Introduction to cryocrystallography

H. Hope and S. Parkin

Since about 1985, low-temperature methods in biocrystallography have evolved from stumbling experimentation to mainstay production techniques. This would not have happened without good reason. Most of the early development was done with nitrogen cooling. More recently, temperatures as low as 5 K have become accessible by means of liquid-helium-based techniques. A brief discussion of the methods, equipment and advantages of data collection at cryogenic temperatures is given.

10.1.1. Cooling of biocrystals

10.1.1.1. *Physical chemistry of biocrystals*

Crystals are normally brought from room temperature to the working, low temperature by relatively rapid cooling, either in a cold gas stream, or by immersion in a cryogen such as liquid nitrogen or liquid propane. One goal of the procedure is to avoid crystallization of any water present in the system, whether internal or external to the crystal. Ice formation depends on the formation of nuclei. Nuclei are formed either by homogenous nucleation, *i.e.* in bulk liquid, or by heterogeneous nucleation, *i.e.* at the surface of a phase other than the liquid. Although data pertaining to biocrystals are scarce, indications are that internal nucleation, whether homogenous or heterogeneous, is not common. Proteins that induce nucleation at mild supercooling are known, so presumably there exist regions in these proteins that help to prearrange water molecules so that they readily form ice nuclei. There are also proteins that hinder nucleation. At present there is no basis for predicting the outcome of cooling for any given protein crystal. Only in a statistical sense can one be reasonably confident that a given macromolecule will not promote the freezing of water.

Vali and coworkers (Götz *et al.*, 1991; Vali, 1995) have provided a quantitative treatment of ice nucleation that can serve as a guideline. They observe that the absolute rate of formation of nuclei increases with the volume of water and with decreasing temperature. The probability p that a volume V of water will begin freezing during a time span t is given by

$$p = J(T)Vt,$$

where $J(T)$ is the nucleation rate at temperature T. Based on empirical data, $J(T)$ is given by

$$J(T) = 6.8 \times 10^{-50} \exp[3.9(273 - T)],$$

where J is in $\mathrm{m^{-3}\,s^{-1}}$ and T is in K. Note that $J(T)$ increases by a factor of 50 per K. As a practical limit, bulk water cannot be cooled below 233 K without freezing. However, given a sufficiently small volume and high cooling rate, it is possible to supercool water to form a glassy state that is at least kinetically stable. Stability requires a temperature below 140 K; at higher temperatures crystallization eventually takes place. For the cooling rates typically attained with small crystals (up to a few hundred K $\mathrm{s^{-1}}$) it seems impossible to avoid crystallization of water in the mother liquor adhering to a crystal, unless it is modified in some way. Once ice forms at the crystal surface, freezing may propagate through the entire crystal, effectively destroying it. Even if the crystal remains intact, diffraction from polycrystalline ice will render parts of any data set from that crystal useless. Because the probability of a nucleation event increases with time, it seems prudent to use a rapid cooling process. However, we note that the expression for $J(T)$ is formulated for pure water and cannot be valid for all conditions; it is well established that a majority of biocrystals can be cooled below 140 K.

A consequence of the foregoing is that for prevention of ice growth one should first focus attention on the region immediately outside the crystal, rather than on its interior. Two approaches have been shown to have merit: (*a*) modification of the solvent layer, and (*b*) removal of the solvent layer.

The goal of solvent modification is to prevent ice formation in that layer. Commonly used modifiers (referred to as antifreezes or cryoprotectants) are water-soluble organic compounds of low molecular weight with good hydrogen-bonding properties; examples include glycerol, ethylene glycols and MPD (2-methylpentane-2,4-diol). These compounds are added to reach a concentration sufficient to suppress nucleation and thereby prevent ice formation. Typical concentrations are in the 15–30% range, depending on the compound and the original composition of the mother liquor. The required concentration must be determined by experiment. Some suitable starting points are given by Garman & Mitchell (1996). The modified solution is tested by cooling a small drop to the working temperature. If the drop remains clear, there is no ice formation.

It is important to keep in mind that any change in the properties of the medium surrounding the crystal will have consequences for its crystallographic stability. In order to protect the crystal, two fields should be considered: thermodynamics and kinetics.

For a crystal in equilibrium with its mother liquor, the chemical potential of each species will be the same inside the crystal and in the mother liquor. If the solution surrounding the crystal is altered by the addition of an antifreeze, the chemical potential μ of water (and other species) will change and the crystal will no longer be in equilibrium with its surrounding solution. The typical result is that $\mu(\mathrm{H_2O}, \text{solution})$ decreases, so $\mu(\mathrm{H_2O}, \text{crystal}) > \mu(\mathrm{H_2O}, \text{solution})$ and there will be a thermodynamic drive to remove water from the crystal. The activation energy for water diffusion is low, so if the process is allowed to proceed, the end result is loss of water with likely deterioration in crystal quality (but see below). Considerations of this kind led Schreuder *et al.* (1988) to develop procedures for solvent modification that would prevent destruction of the crystal. Although some success was reported, sufficient problems were encountered that the approach cannot be considered to be a general solution.

Copyright © 2012 International Union of Crystallography

It is important to note that loss of water does not always lead to loss of crystal integrity. For example, Esnouf *et al.* (1998) and Fu *et al.* (1999) have shown that controlled dehydration can result in substantially improved resolution. In addition, antifreeze concentrations much higher than those needed to suppress ice formation (Mitchell & Garman, 1994) can preserve low mosaic spread. Work by Kriminski *et al.* (2002) suggests these phenomena may be connected.

In earlier work, Travers & Douzou (1970) emphasized the importance of keeping the dielectric constant unchanged when modifying the mother liquor. Petsko (1975) made observations that support the significance of this approach and, based on systematic studies, also showed that keeping $\mu(\mathrm{H}^+)$ constant is of great importance. Hui Bon Hoa & Douzou (1973) and Douzou *et al.* (1975) have presented tables of solvent compositions that facilitate the preparation of successful cryoprotective solutions. It should be noted that a significant aim in Petsko's work was to keep the solvent liquid, so as to permit manipulation of enzyme substrates. Studies of enzyme kinetics are much more demanding than the rapid cooling to about 100 K that is of primary interest here.

In most cases it is only necessary to consider kinetic effects, *i.e.*, how long it takes before the crystal itself begins to change. When a crystal in a drop of its original mother liquor is dipped into a drop of modified mother liquor, diffusion begins immediately. The speed of propagation in the liquid phase can be estimated from a standard equation for the mean-square travel distance of a diffusing species,

$$\overline{x^2} = 2Dt,$$

where D is the diffusion coefficient and t is the the time. Typical room-temperature values for D for antifreeze molecules in water are around 10^{-9} m^2 s^{-1}. Thus, a root-mean-square travel distance of 0.1 mm requires about 5 s. For a solvent layer about 0.1–0.2 mm thick, a contact time of 5–20 s should provide a sufficient level of modification to prevent freezing, while the risk of crystal damage is small. It is often important to stop any ongoing process as soon as protection from freezing has been attained. This can conveniently be achieved by immersion in liquid N_2.

10.1.1.2. Internal ice or phase transition

If there are good indications that ice formation does start internally, or that a destructive phase transition takes place, an attempt can be made to modify the internal water structure. An important consideration of Petsko (1975) was never to allow large deviations from equilibrium. This can be accomplished by a slow, gradual change in $\mu(\mathrm{H_2O}$, solution), allowing enough time for the crystal to re-establish equilibrium. A number of successful experiments were reported.

10.1.1.3. Removal of the solvent layer

Because of their tendency toward rapid loss of internal solvent, biocrystals rarely survive prolonged exposure to the atmosphere. A solution to this problem was described by Hope (1988), where the solvent is removed while the crystal is submerged in a hydrocarbon oil. After the liquid has been removed, a small drop of oil is allowed to encapsulate the crystal, allowing it to tolerate brief exposure to air. Even under such mild conditions, some crystals still lose water and suffer damage. A remedy for this is to keep the oil saturated with water. One disadvantage of the oil technique is the tendency of loop mounts to carry along too much oil (Teng, 1990), which can cause excessive background scattering. An advantage is that absorption can become nearly isotropic. The most commonly used oil is the polyisobutene Infineum V8512, formerly known as Infineum Parabar 10312, Exxon Paratone-8277 or Paratone-N. Contrary to popular myth, there is nothing magical or mysterious about this particular oil. Important properties are that it is inert, has a useful viscosity, forms a glass on cooling and has a coefficient of thermal expansion which appears to match that of many biocrystals.

10.1.1.4. Cooling rates

The time dependence of nucleation probability suggests that faster is safer. Although few systematic data are available, it is commonly assumed that crystal cooling should be as rapid as possible. Studies related to cryopreservation of biological samples for electron microscopy provide a number of measurements of cooling rates in various coolants, but it is difficult to extract information directly relevant to cryocrystallography. From a practical point of view, the coolants to be considered are liquid N_2 and liquid propane (and, to a lesser extent, liquid ethane). Thermal conductivities for small-molecule compounds in liquid form tend to be of similar magnitude – around 1.5×10^{-5} W m^{-1} K^{-1}. N_2 boils at 77 K; propane remains liquid between 83 and 228 K. It is often thought that the gas layer that can form around an object dipped in liquid N_2 as a result of the Leidenfrost effect (Leidenfrost, 1756) makes liquid N_2 less effective as a coolant than liquid propane, which is much less likely to form bubbles. However, from model calculations, Bald (1984) suggested that this Leidenfrost insulation problem in liquid N_2 would not be significant in the cooling of small objects of low thermal conductivity, because there is not enough heat transport to the surface to maintain the gas layer. He also concluded that liquid N_2 could potentially yield the highest cooling rate among commonly used coolants, but in a review of plunge-cooling methods, Ryan (1992) gives preference to liquid ethane. Walker *et al.* (1998) measured the cooling rates in N_2 gas (100 K), liquid N_2 (77 K) and liquid propane (100 K) of a bare thermocouple and of a thermocouple coated with RTV silicone cement. The thermocouples were made from 0.125-mm wire and the coating was about 0.20–0.25 mm thick. With the gas stream, cooling of the centres of the samples from 295 to 140 K took 0.8 and 2 s, respectively; with liquid N_2 the times were 0.15 and 0.6 s, and with liquid propane they were 0.15–0.18 and 1.2 s (time reproducibility is to within ±10%). Given the simplicity of liquid-N_2 immersion, there seems little reason to choose the more complicated and more hazardous liquid-propane technique. As the field of low-temperature biocrystallography has matured, liquid-propane methods have all but died out, and liquid-N_2 immersion is now by far the most commonly employed method.

10.1.2. Beneficial effects of low temperature

10.1.2.1. Suppression of radiation damage

Biocrystals near room temperature are sensitive to X-rays and generally suffer radiation damage during data measurement. Often this damage is so rapid and severe that a number of different crystals are needed for a full data set. On occasion, damage is so rapid that data collection is impossible. Crystal decay is typically accompanied by changes in reflection profiles and cell dimensions, which alter the positions of diffraction maxima, exacerbating the problem of changing diffraction intensities. The use of more than one crystal invariably introduces inaccuracies. Intensities from a crystal near the end of its usable life will have decay errors. Individual samples of biocrystals frequently have measurable differences in structure; merging of data will result in an average of the structures encountered, with concomitant loss of definition. Crystals cooled to near liquid-N_2 temperature typically show a greatly reduced rate of radiation damage, often to the extent that it is no longer an issue of major concern. The protection from radiation damage was noted early on (Haas & Rossman, 1970) and numerous cases were observed by Petsko (1975). A noteworthy example is the successful prevention of radiation damage to crystals of ribosome particles (Hope *et al.*, 1989).

Radiation damage appears to be most commonly initiated by photoelectrons and propagated by their inelastic scattering from nearby atoms, creating positively charged species and a cascade of secondary electrons (Garman & Nave, 2009). These can further interact with either protein or with water to form reactive, charged species and free radicals. At sufficiently low temperature, two effects can influence the rate of damage: movement of the reactive species is impeded and the activation energy for reaction is not available. A revealing observation has been described by Hope (1990), where a crystal that had been exposed to synchrotron radiation for many hours at 85 K showed no overt signs of radiation damage, but as the crystal was being warmed toward room temperature, it suddenly turned black and curled up like a drying leaf. More commonly, crystals turn yellow under X-ray irradiation, and bubbles and cracks appear on warming. The rate of free-radical formation would be little affected by temperature, so that when sufficient mobility and activation energy become available, the stored radicals will react.

There is a general consensus that radiation damage, even in high-flux synchrotron beams, can be slowed by cooling to liquid-helium temperatures. The extent of radiation damage is expected to depend on the nature of the macromolecule, and literature examples clearly illustrate this. Meents *et al.* (2007) have reported an extensive study of insulin and holoferritin at 15 and 90 K. They observed statistically significant but relatively small reductions in radiation damage; for holoferritin, 23% less damage at the lower temperature, and for insulin about 6%. In a study of *Streptomyces rubiginosus* D-xylose isomerase, Chinte *et al.* (2007) found a lifetime extension of 25% at 8 K compared to data collection at 100 K. Corbett *et al.* (2007) compared results from data collected at ~40 and at 110 K in a study of the metalloprotein putidaredoxin. They report that radiation-induced photoreduction at 110 K resulted in misleading structure interpretation. At 40 K the photoreduction did not occur. The damage mechanism in this case is related to a change in oxidation state of a central metal atom. The authors made a strong argument for measuring data for metalloproteins at the lowest possible temperature. Chinte *et al.* (2007) pointed out that the additional cost of liquid-helium-temperature measurements compared to 90–100 K measurements is small, and that the advantages can significantly outweigh the increased cost.

In recent years, the ability to calibrate X-ray beam intensity, to calculate reasonable approximations to accumulated radiation dose and to assess crystal degradation by means of various spectroscopies (*e.g.* UV–visible, IR, Raman, XAFS, XANES) in concert with diffraction has brought dramatic advances in understanding radiation damage by X-rays. A concise account has been given by Garman & Nave (2009). Useful suggestions for avoidance of radiation damage, including cases where multiple crystals are required, have been given by Holton (2009). Briefly, knowledge of beamline photon flux density (photons $\mu m^{-2}\, s^{-1}$), the dose ratio (a function of crystal composition and X-ray wavelength), the crystal shape and the cross section intensity profile of a given X-ray beam allows an estimate of the maximum tolerable exposure time for a particular crystal.

10.1.2.2. Mechanical stability of the crystal mount

The mechanical stability of samples is also of concern. Crystals mounted in capillaries and kept wet are prone to movement, giving rise to difficulties with intensity measurements. A crystal at cryotemperature is rigidly attached to its mount; slippage is impossible.

10.1.2.3. Effect on resolution

The effects on radiation damage and mechanical stability are clear-cut, and provide the main reasons for using cryotechniques. Resolution can also be affected, but the connection between temperature and resolution is neither simple nor obvious.

In any crystal, the Boltzmann distribution law is an important factor in determining the accuracy of the replication of structure from one unit cell to another. For many small-molecule crystals, just one arrangement corresponds to a distinct energy minimum. The result is a well ordered structure. With macromolecules, the typical situation is one where a number of arrangements correspond to similar energies. Accordingly, a number of atomic arrangements will be expressed in the crystal. Although the relative values of local minima depend on the temperature, one cannot count on a significant change in ordering by cooling the crystal. Instead, some distribution will be frozen in.

If poor resolution is the result of rapid radiation damage, data collection at cryotemperature can lead to much improved resolution. However, if poor resolution is caused mainly by inexact replication from one unit cell to another, lowering the temperature may have little effect on resolution. If the mosaic spread in the crystal increases upon cooling, resolution may even deteriorate.

In a model proposed by Hope (1988), a relationship between resolution r and temperature T is given by

$$r_2 = r_1[(B_0 + bT_2)/(B_0 + bT_1)]^{1/2}.$$

Here r_1 is the resolution at T_1, r_2 is the resolution at T_2, B_0 is the value of B at $T = 0$ and b is a proportionality constant. There are two underlying assumptions: (1) the overall atomic distribution does not change significantly with temperature and (2) for any given T, the temperature factor [*i.e.* $\exp(-B\sin^2\theta/\lambda^2)$] at the resolution limit has the same value; thus the effects of scattering factors and Lorentz–polarization factors are ignored. We see that if B_0 is the predominant term, lowering T will not have much effect, whereas for small B_0 (a relatively well ordered structure) the effect of T on r can be large. For example, if the room-temperature resolution is 1.5 Å, the resolution at 100 K can be around 1 Å, but if the room-temperature resolution is around 3 or 4 Å, little change can be expected. A qualitative assessment of these effects was clearly stated by Petsko (1975).

10.1.2.4. Annealing of biocrystals

Prior to about 1996, it was thought that thawing of a flash-cooled crystal would inevitably lead to its demise. In spite of anecdotal evidence that some biocrystals could survive warming and re-cooling, this notion persisted until work by Harp *et al.* (1998) and by Yeh & Hol (1998) showed that some biocrystals could be annealed under certain well defined conditions. The method of Harp *et al.* (1998) involved transfer of a flash-cooled crystal from the cold stream to a cryoprotective solution at room temperature for 3 min followed by a second flash cooling. The Yeh & Hol (1998) technique, on the other hand, is performed *in situ* by simply blocking the cold stream for 1–2 s (*i.e.* until melting is observed), after which time the blockage is removed to re-cool the sample. Both these annealing protocols were shown to be capable of dramatic improvements in diffraction quality, both in terms of reduced mosaicity and improved resolution. A plausible mechanism involving the release of cooling-induced lattice stress by defect migration and solvent transport was suggested by Kriminski *et al.* (2002). Other work (Parkin & Hope, 2003; Juers & Matthews, 2004; Weik *et al.*, 2005) supports the notion of solvent transport, possibly as a result of solvent crystallization (Weik *et al.*, 2001) or other phase transition (Parkin & Hope, 2003) in the aqueous regions within biocrystals.

10.1.2.5. Additional benefits from sub-77 K cooling with helium

As is the case with nitrogen cooling, it is unlikely that thermodynamic equilibrium will be reached by cooling to liquid-helium temperatures. The change that will certainly take place on cooling to liquid-helium temperature is that true thermal motion will be greatly reduced. One result of this is that individual atom peaks will become much sharper. For example, electron-density maxima for well ordered atoms will increase by a factor of about three on cooling from 90 to 10 K. Potentially, this can allow a more detailed interpretation of a structure with a resolution limit better than about 1.5 Å, and also for the better ordered regions of a structure with poorer overall resolution. In general, however, it is not realistic to expect a significant resolution improvement in low-resolution structures based on the effects of temperature alone. Improvements related to diminished radiation damage, on the other hand, can be significant. Two studies illustrate the effects discussed here.

The effects of helium cooling on a high-resolution structure are well illustrated in a study by Petrova *et al.* (2006). They studied a complex of human aldose reductase at 15, 60 and 100 K. The complex has yielded data to 0.66 Å resolution, and thus represents a generally highly ordered structure. The emphasis of the study was on the behaviour of the atomic displacement parameters (ADPs). It was found that the major ADP component for well ordered atoms is temperature driven, as it would be in normal small-molecule structures. A large proportion of the atoms at 15 K have B values of 2 Å^2 or less (about 0.025 Å^2 or less in terms of U values). At 100 K, the corresponding cutoff is about 5 Å^2. Cooling to 15 K allows large portions of the structure to be determined with a precision that would be considered excellent for small molecules. However, the average isotropic B value for the 'best' Cα atoms at 15 K is still 3.9 Å^2 (a U value of about 0.05 Å^2). This indicates that the positional parameters for many of these atoms in reality are composites of closely spaced positions. The best average protein ADPs at 15 K are about the magnitude of small-molecule ADPs at room temperature. This sets unfortunate limits to the attainable accuracy of structural and electron-density parameters.

Hexagonal hen egg-white lysozyme has a relatively well ordered structure, but there are significant regions with multiple conformations. Brinkmann *et al.* (2006) measured diffraction data at 10 K to a resolution limit of 1.46 Å. The results indicate that major areas of disorder are present, illustrating that structural disorder persists at the lowest temperatures.

Although helium is more expensive than nitrogen as a coolant, the added cost for a helium-temperature data set is usually trivial. Equipment design and operating methods have developed to a stage where there is no significant operational difference between nitrogen and helium cooling when manual crystal handling is used.

10.1.3. Principles of cooling equipment

There are many ways to construct a low-temperature apparatus based on the cold-stream principle that functions well, but they are all made according to a small number of basic principles.

All gas-stream crystal-cooling devices must have three essential components: (*a*) a cold gas supply, (*b*) a system of cold gas delivery to the crystal, and (*c*) a system for frost prevention at the crystal site.

10.1.3.1. Liquid-nitrogen-based cold gas supply

Historically, two methods were commonly used: generation of gas by boiling liquid N_2 with an electrical heater, and cooling of a gas stream in a liquid-N_2 heat exchanger. The currently common methods are boiling, and cooling of the gas by means of a refrigerator.

Because precise voltage and current control are easily realized, the boiler method has the advantage of providing very accurate control of the flow rate with minimal effort. Precise control of the flow rate is typically not attained when the rate is controlled with standard gas-flow regulators, because they control volume, not mass.

In addition to control of the flow rate, precise control of the temperature requires exceptional insulation for the cold stream. The longer the stream path, the higher the requirements for insulation. As a rule, temperature rise during transfer should not exceed 15 K at a flow rate of 0.2 mol N_2 min^{-1}; preferably, it should be significantly lower. Higher cooling loss leads to excessive coolant consumption and to instability caused by changes in ambient temperature. High flow rates may also tend to cause undesirable cooling of diffractometer parts.

Appropriate insulation can be readily attained either with silvered-glass Dewar tubing or with stainless-steel vacuum tubing. Glass has the advantage of being available from local glassblowing shops; it generally provides excellent insulation. The main disadvantages are fragility and a rigid form that makes accurate positioning of the cold stream difficult. Stainless steel can provide superb insulation, given an experienced manufacturer. A major advantage is the availability of flexible transfer lines that greatly simplify the positioning of the cold stream relative to the diffractometer.

10.1.3.2. Liquid-helium-based cold gas supply

Open-stream cooling devices that can reach temperatures around 5 K are now commercially available. In principle, the design is simpler than that for liquid-nitrogen-based devices. A basic cooling apparatus consists of a liquid-helium transfer line from a pressurized delivery tank, an evaporation chamber and a cold gas delivery tube. The transfer line is an insulated capillary tube. The delivery tube is an insulated stretch of vacuum tubing with an electrically heated nozzle at the exit. The helium flow is controlled with a needle valve. Because of thermal loss, the flow rate also largely determines the temperature in the range below 20 K. Above about 20 K, an in-stream heating element is used for additional temperature control. This is necessary, because if the flow rate is too low, the cooling stream becomes unstable and will not reliably cover the sample.

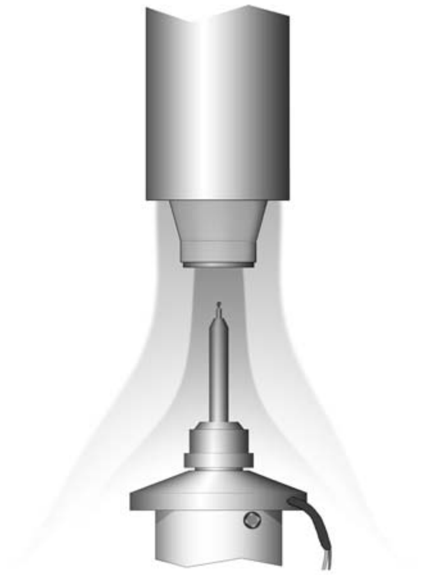

Figure 10.1.4.1
Schematic drawing of a dual-stream setup with the streams parallel to the diffractometer φ axis. The top part represents the outlet end of the stream delivery device. The outer stream (lighter grey) is dry, warm air. The goniometer head is protected by a shield.

For a given setting of the flow control valve, the flow rate depends on the tank pressure. For a constant temperature, a constant pressure is required. The pressure is controlled with a pressure regulator that can reduce the tank pressure by releasing helium gas or raise it by adding helium gas from an external helium supply source. A typical delivery tank pressure is around 20 kPa. It is very important that the pressure is constant. The precise value attained is less important.

At atmospheric pressure, helium at around 40 K has the same density as room-temperature air. This means that very cold helium will rise in air, and has the capacity to seriously cool instrument parts in its way. Goniometer heads, beam stops and beam collimators are particularly vulnerable. A simple remedy is to use a small fan to mix the cold helium with room air.

10.1.3.3. *Frost prevention*

Three areas must be kept frost-free: the crystal, the crystal mount and the delivery end of the transfer tube. The first successful solution to this problem was the dual-stream design of Post *et al.* (1951). It provides for a cold stream surrounded by a concentric warm stream. If the warm stream is sufficiently dry, this will prevent frost around the outlet. The crystal will remain frost-free only if mixing of the two flows occurs downstream from the crystal. For a stream aligned with the axis of the goniometer head, an additional shield is needed to keep the goniometer head frost-free.

10.1.4. Operational considerations

10.1.4.1. *Dual-stream instruments*

Fig. 10.1.4.1 shows a schematic drawing of the region around the crystal in a traditional dual-stream apparatus, first described by Post *et al.* (1951). The device provides for a cold stream surrounded by a concentric warm stream. The diameter of the cold stream is typically around 7 mm with a shield stream of 2–3 mm. The two streams flow parallel to the axis of the crystal mount. In a properly functioning apparatus, the warm stream supplies enough heat to keep the tip of the cold-stream tube above the dew point. It is important that the streams do not mix, or the crystal temperature will not be stable. This is achieved by careful balancing of flow rates to minimize turbulence. (Absence of turbulence can be judged by the shape of the shadow of the cold stream in a parallel beam of bright light.) In a laminar cold stream, the crystal is well protected and no special precautions are needed. The region of constant, minimum temperature will typically have a diameter of about 3 mm. Turbulent flow will result in the absence of any constant-temperature region, so it is vitally important to verify the stream quality.

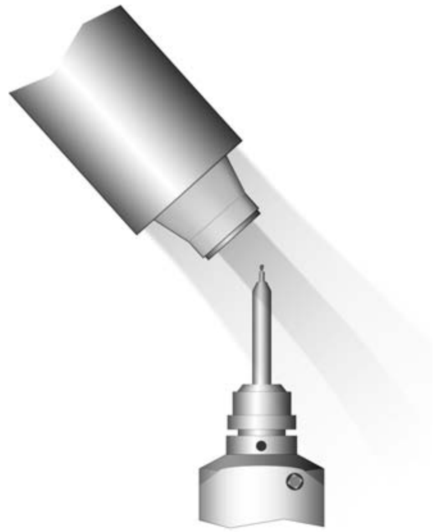

Figure 10.1.4.2
Schematic drawing of a dual-stream setup with the streams angled relative to the diffractometer φ axis. Stream representations are the same as in Fig. 10.1.4.1. The cold stream misses the goniometer head, so no shield is required.

The cold stream has sufficient heat capacity to cool down the goniometer head, and sometimes other adjacent equipment parts as well. A simple solution consists of an aluminium cone equipped with a heating coil on the back. A shield that functions well has been described by Bellamy *et al.* (1994).

Fig. 10.1.4.2 illustrates a situation where the stream direction deviates substantially from the head-on direction in Fig. 10.1.4.1. An angle of 35–55° will give good results. An advantage of an angled delivery is that the cold stream will not touch the goniometer head, and therefore the heated stream deflector is not needed, resulting in simplified installation and operation.

Analysis of the dual-stream apparatus reveals a twofold function of the outer stream: it keeps the nozzle frost-free and it supplies heat to the mounting pin. Protection of the crystal is, in reality, already provided by the laminar cold stream. The nozzle can be kept frost-free simply with an electric heater. Ice formation on the crystal mount can be easily suppressed by appropriate design of the mounting pin and mounting fibre, and attention to their interaction with the cold stream. A successful solution is sketched in Figs. 10.1.4.3 and 10.1.4.4.

10.1.4.2. *Electrically heated nozzle*

Fig. 10.1.4.3 shows the functional equivalent of Fig. 10.1.4.1. Instead of the warm stream, an electrical heating element is used to keep the tip of the delivery tube ice free. An actual construction will usually consist of a nozzle that can be attached to the delivery tube. The heating element is made from standard resistance wire (*e.g.* Nichrome). About 5 W will usually be

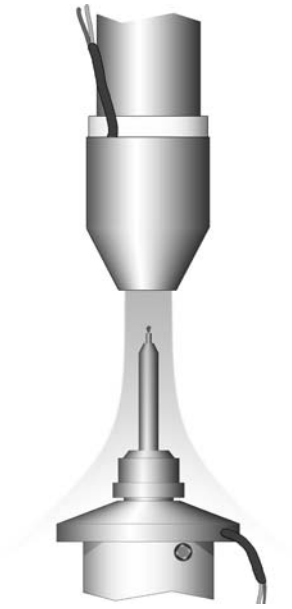

Figure 10.1.4.3
Schematic drawing of a single-stream setup with the stream parallel to the diffractometer φ axis. The cold stream is represented by a grey region. The nozzle is heated above the dew point with a heating coil. The goniometer head is protected by a shield.

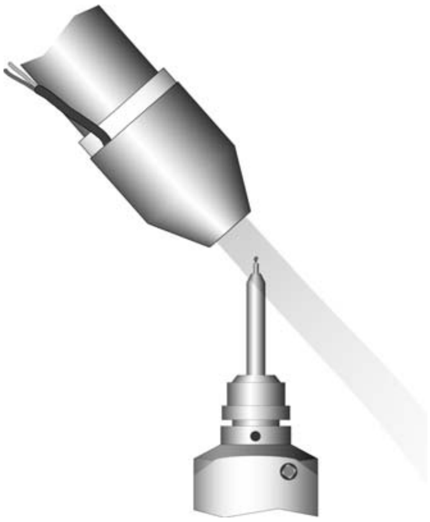

Figure 10.1.4.4
Schematic drawing of a single-stream setup with the stream angled relative to the diffractometer φ axis. The cold stream is represented by a grey region. The crystal mounting pin protrudes 1–2 mm into the cold stream. This prevents frost from forming on the mounting fibre. The nozzle is heated above the dew point with a heating coil. The cold stream misses the goniometer head, so no shield is required. In general, the simplest operation is attained with a setup similar to that shown here.

enough to prevent frost or condensation. The head-on direction results in reliable frost protection for the crystal, but requires that the goniometer head is equipped with a heated stream deflector.

Fig. 10.1.4.4 shows the functional equivalent of Fig. 10.1.4.2. This arrangement leads to the simplest design, although some precautions are needed. The mounting pin itself supplies the heat needed to prevent ice formation on the pin. The tip of the pin should be smooth in order to prevent turbulence. About 1–2 mm (but not more) of the tip must protrude into the cold stream. If too much of the pin is in the cold stream, the rest of the pin can become too cold and ice up. If the pin is too far out of the stream frost prevention will also fail, because glass or other insulating mounting materials will invariably collect ice at the cold/warm interface. As frost prevention depends on heat conducted from the rest of the pin, it must be made from copper (a requirement not strictly necessary for the dual-stream design). This design has been extensively tested and has been used for many years for the collection of a large number of data sets. Results are uniformly good, with simple operation and reliable frost prevention even in high humidity.

Fig. 10.1.4.5 is a photograph of a laboratory implementation of the setup of Fig. 10.1.4.4, with helium as the coolant. Operation is as simple as with nitrogen cooling.

Omission of the warm stream results in significant design simplification. The entire apparatus for production of the outer stream is left out, resulting in real savings in manufacture, operation and maintenance. There is no obvious disadvantage, as ice protection is as good as with the dual stream. The main cost to the user is in the requirement that the mounting system be constructed within somewhat narrower limits, including the requirement of a copper-shafted mounting pin. The fact that operator errors tend to become apparent through frost formation can actually be an advantage. With a dual-stream device, an improperly positioned cold stream or an improperly prepared crystal mount may not produce overt signs, even though the crystal temperature is ill-defined.

In all configurations shown, correct positioning of the cold stream is essential. The centre of the stream should not miss the centre of the diffractometer (and hence the crystal) by more than 0.5 mm.

With helium, the single-stream technique represents the best solution and reliable frost prevention at temperatures down to around 5 K is easily attained. Crystal mounting is simple and the sample is always visible, simplifying centring. In the authors' experience, liquid-helium cooling is as simple as liquid-nitrogen cooling.

10.1.4.3. Temperature calibration

Measurement of the temperature at the crystal site with sensing devices that require attached leads is very difficult, mainly because of heat conduction along the leads. It is usually necessary to loop the leads into the delivery nozzle.

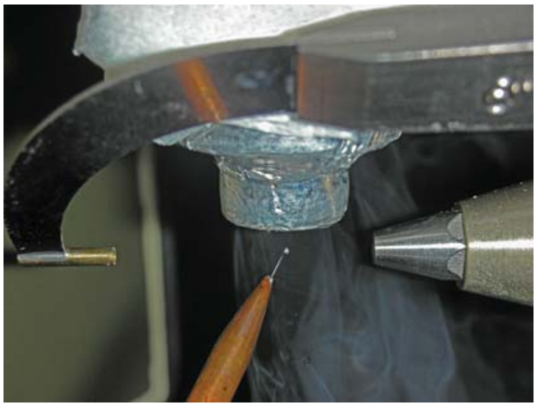

Figure 10.1.4.5
A crystal in a helium stream at 8 K in a setup corresponding to Fig. 10.1.4.4. A thin layer of fog forms at the helium–air interface. The cold stream breaks up well below the crystal position. Rising cold gas (visible as fog to the right of the cold stream) has been mixed with air to prevent cooling of diffractometer parts. The nozzle temperature is 295 K. The crystal is attached to a tapered glass fibre. The light-coloured region at top is not ice; it is part of the insulation. This photograph was taken after the end of data collection.

Both Si diodes and Pt resistance sensors have become sufficiently miniaturized to make them preferred choices at the lowest temperatures. Thermocouples are acceptable above about 80 K. A reliable method of calibration makes use of the known temperature of a phase transition of a crystal in the normal data-collection position. For example, KH_2PO_4 (often referred to as KDP) has a sharp transition at 123 K from tetragonal to orthorhombic, and is commonly used. Another possibility is KH_2AsO_4, which has a corresponding phase transition at 95 K.

Two readout temperatures suffice, one at room temperature and one at the phase transition. The difference between readout temperature and crystal-site temperature can be assumed to vary linearly with T, so interpolation or extrapolation is simple.

10.1.4.4. Transfer of the crystal to the diffractometer

Inspection of Figs. 10.1.4.1–10.1.4.4 reveals that the mounting of a crystal on a mounting pin *via* the traditional placement of the pin in the hole of a standard goniometer head is not simple, because the cooling nozzle is in the way. The solution to the problem is a design that allows side entry. This is most commonly achieved with a magnetic platform on the goniometer head and a corresponding magnetic base on the mounting pin, but an alternative means of side entry employs a slot on a modified goniometer head; the slot is equipped with a spring-loaded catch that allows a very smooth, but stable, catch of the pin.

The use of liquid-N_2 cooling and side entry, and the requirement of reproducible knowledge of crystal temperature at all times, led to the development of a set of tools for crystal mounting as described by Parkin & Hope (1998). The tools include special transfer tongs used for moving crystals from liquid N_2 to the goniometer head. The temperature of the crystal is maintained by the heat capacity and low heat conductance of the tongs. The operation is independent of the orientation of the goniometer head because there is no liquid to contain.

10.1.4.5. Automated robotic crystal handling

The era of structural genomics has necessitated a move to high throughput at high-intensity synchrotron sources. To meet this goal, a number of robotic crystal-handling devices have been developed. These in turn have had the beneficial effect of increased standardization in mounting-pin geometry.

10.1.5. Concluding note

With correctly functioning low-temperature equipment and appropriate techniques, a crystal can be maintained frost-free for the duration of a data-collection run. Formation of frost on the crystal indicates malfunction of the equipment, or operator error. The most likely cause is operator error, but faulty equipment cannot be ruled out. The techniques described here have been used for collecting thousands of data sets from ice-free crystals and crystal mounts. There is no reason to accept frost problems as an unavoidable part of cryocrystallography.

Chapter 10.2. Cryocrystallography techniques and devices

D. W. Rodgers

10.2.1. Introduction

The ability to collect X-ray data from macromolecular crystals at cryogenic temperatures has played a key role in the more widespread and effective use of crystallography as a tool for biological research. Radiation-damage rates are greatly reduced at low temperature, often by orders of magnitude, making it possible to work with crystals that would otherwise diffract too weakly or decay too quickly. In particular, this radiation protection is essential for the full use of increasingly powerful synchrotron-radiation sources, and the coupling of the two permits the investigation of ever larger macromolecular complexes and the collection of higher-resolution data from nearly all samples. Cryogenic data collection has also allowed efficient experimental phasing using multiple-wavelength methods, as well as preservation of unstable samples and trapping of transient enzyme intermediates, an area that will undoubtedly continue to gain in importance.

In this chapter, practical aspects of cryocrystallography are discussed, with an emphasis on techniques and devices for crystal preparation and handling. A number of prior reviews covering these and other aspects of macromolecular cryocrystallography are available (Hope, 1988, 1990; Watenpaugh, 1991; Rodgers, 1994, 1997; Abdel-Meguid *et al.*, 1996; Garman & Schneider, 1997; Parkin & Hope, 1998). Radiation-damage protection at low temperature, which is not well understood, has also been discussed (Henderson, 1990; Gonzalez & Nave, 1994; Rodgers, 1996; Garman & Schneider, 1997), and the principles and operation of cryostats for sustained cooling during data collection are described elsewhere (Rudman, 1976; Hope, 1990; Garman & Schneider, 1997).

10.2.2. Crystal preparation

Macromolecular crystals are intimately associated with bulk aqueous solution. It surrounds them and penetrates them as solvent-filled channels, which typically account for 30–80% of the crystal volume. A key goal, therefore, of any procedure for cooling these samples to cryogenic temperatures is to prevent the formation of hexagonal crystalline ice. Ice formation, because of the associated increase in specific volume, inevitably disrupts the order of the macromolecular crystals and renders them useless for data collection. The principle that underlies current methods is that sufficiently rapid cooling causes the formation of a rigid glass before ice nucleation can occur. The high viscosity of the glass then prevents subsequent rearrangement into an ordered lattice. Early attempts to flash cool macromolecular crystals were made by Low *et al.* (1966), Haas (1968), and Haas & Rossmann (1970).

With samples as large as macromolecular crystals, however, it is not possible to achieve the high cooling rates necessary to prevent ice formation in water and most aqueous crystallization solutions. The most general method for overcoming this problem is to equilibrate the crystal with a solution containing a cryoprotective agent that slows ice nucleation and allows the formation of a glassy solid with attainable cooling rates. A list of cryoprotectants used successfully with macromolecular crystals is shown in Table 10.2.2.1. Typically, these cryoprotectants are included in the established stabilization or harvest solution at concentrations that range from 6–50%. Glycerol is frequently chosen for initial trials and appears to be a widely applicable cryoprotectant for both salt and organic precipitants. Concentrations of glycerol necessary to prevent ice formation in a number of typical crystallization solutions have been tabulated (Garman & Mitchell, 1996). Other compounds such as ethylene glycol and small sugars fall into this same class. Crystallization precipitants such as 2-methyl-2,4-pentanediol (MPD) or polyethylene glycol (PEG) can often simply be increased in concentration to provide sufficient cryoprotection. Ethanol, methanol and MPD are useful in relatively low-salt conditions. The listed stereoisomer of butanediol is a particularly effective cryoprotectant and can be used where other components of the solution, such as high salt, may limit the amount of cryoprotectant that can be added. Limitations owing to salt in the crystallization mix can also be overcome by transferring the crystals to a solution containing an organic precipitant before or during the introduction of the cryoprotectant (Singh *et al.*, 1980; Ray *et al.*, 1991; Wierenga *et al.*, 1992). Combinations of cryoprotectants have been used where a single cryoprotectant alone did not permit successful flash cooling.

It is rare that a crystal can be transferred without damage directly to a solution containing full-strength cryosolvent. Usually, the cryoprotectant must be introduced slowly to reduce stress on the crystal lattice. Methods of introducing cryoprotectant-containing solutions are listed in Table 10.2.2.2. Techniques such as serial transfer through increasing cryoprotectant concentrations or dialysis are preferred. They allow the crystal to equilibrate with the cryosolvent, leading to reproducible crystal quality and unit-cell dimensions after flash cooling. Also, with equilibrium methods, the solution conditions can be altered in an

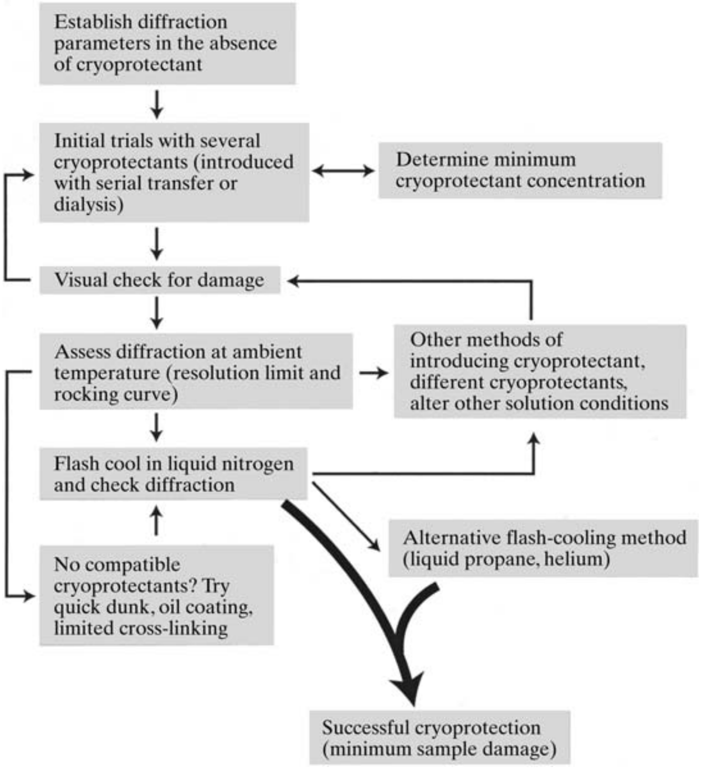
attempt to control any crystal damage associated with the flash-cooling process itself. The best scheme for serial transfer must be determined empirically. Equilibration time at each step depends on a number of factors (size of the crystals, solvent content, viscosity of the solution) but can be as rapid as less than a minute for small cryoprotectants or as long as hours for large polymers (Bishop & Richards, 1968; Fink & Petsko, 1981; Ray *et al.*, 1991). Typically, 5% increments in cryoprotectant concentration with equilibration times of 15 min or longer at each step are used in initial trials. The step size is then decreased if damage occurs. Dialysis can be done conveniently in the small buttons used for crystallization. These are available with chamber sizes as low as 5 µl and allow a piece of dialysis membrane to be stretched and held securely over the opening. Dialysis times range from 1 to 24 h depending on the size of the cryoprotectant and the viscosity of the solution.

Another technique, growth of the crystals directly in cryoprotectant solutions, is particularly convenient and effective. In some cases, the primary precipitant, MPD for example, may provide cryoprotection if the concentration used in crystallization is sufficiently high. More commonly, however, additives such as glycerol are included in the crystallization buffer. An advantage of this technique is that crystals can be mounted directly from the crystallization drop, eliminating potential damage in transferring to a harvest or cryoprotective solution.

When it is not possible to identify a cryosolvent compatible with the crystals, a brief exposure to the cryoprotective solution may allow successful flash cooling. Apparently, the water in crystal solvent channels is constrained sufficiently to prevent nucleation, and simply exchanging the external aqueous solution with cryosolvent provides protection. The 'quick dunk' in the cryosolvent may be as short as a few seconds, and for some crystals it is possible to combine this technique with prior equilibration in lower, non-damaging concentrations of cryoprotectant. The same principle of preventing ice formation in the external solution forms the basis of an alternative technique developed by Hope (1988). Here, the external solution is replaced by a hydrocarbon oil before flash cooling.



Establish diffraction parameters in the absence of cryoprotectant
Initial trials with several cryoprotectants (introduced with serial transfer or dialysis)
Determine minimum cryoprotectant concentration
Visual check for damage
Assess diffraction at ambient temperature (resolution limit and rocking curve)
Other methods of introducing cryoprotectant, different cryoprotectants, alter other solution conditions
Flash cool in liquid nitrogen and check diffraction
Alternative flash-cooling method (liquid propane, helium)
No compatible cryoprotectants? Try quick dunk, oil coating, limited cross-linking
Successful cryoprotection (minimum sample damage)

Figure 10.2.2.1
Recommended pathway for optimizing cryoprotectant conditions and flash cooling.

Finding suitable cryoprotection conditions is a trial-and-error process. Two problems must be overcome: the cryoprotectant must be introduced without significant damage to the crystal, and damage during the flash-cooling process must be minimized. A scheme for systematically determining conditions for flash cooling is given in Fig. 10.2.2.1. In order to assess the effect of subsequent manipulations, it is important first to establish the resolution and rocking curve of the crystals under normal harvest conditions. Then one or a few cryoprotectants can be added to the harvest solution under conditions that allow equilibration with the crystal. The minimum concentration of cryoprotectant necessary to prevent ice formation can be determined by flash cooling candidate solutions using the loop-mounting technique described in Section 10.2.3. A sufficient concentration of cryoprotectant will result in a transparent glass upon cooling, while too low a concentration will produce opaque microcrystalline ice. A solution of cryoprotectant 2–3% above this minimum value should be used to allow for the added volume and therefore slower cooling when the crystal is present. If the crystals crack or dissolve in a cryosolvent, then the cryoprotectant should be introduced more slowly, the solution conditions (precipitant concentration, ionic strength, pH) altered, or the cryoprotectant eliminated from consideration.

The diffraction quality of crystals that show no visible sign of damage should be assessed at the crystal-growth temperature, and solution conditions should be altered if there has been a significant loss in resolution or an increase in rocking-curve width. For crystals that are incompatible with a wide range of cryosolvent conditions, quick-dunk and oil-coating techniques should be considered. Limited cross-linking (with glutaraldehyde, for example) can sometimes stabilize crystals for the introduction of cryoprotectant or improve stability during flash cooling.

When conditions that result in little or no damage have been identified, the crystals should be flash cooled and the diffraction assessed again. The formation of even small amounts of microcrystalline ice can be detected after flash cooling as characteristic powder rings at low-order spacings of 3.90, 3.67, 3.44 Å. If ice forms, a greater concentration of cryoprotectant must be used. An increase in the rocking-curve width of the crystal at this stage is common, probably due to the thermal stress on the lattice or changes in solution properties on cooling. If this increase is more than 50%, or if any loss of resolution occurs, solution conditions should be altered and the process repeated. The concentration of the cryoprotectant can be increased and different cryoprotectants tested. Other solution parameters, as noted above, can also be adjusted in an attempt to decrease the damage from flash cooling. In addition, different flash-cooling techniques (discussed below) can be tested to determine whether they produce less damage. Suitable cryosolvent conditions are usually established after a few trials, and even in difficult cases it has generally proven possible to find acceptable conditions by continuing to refine solution parameters.

10.2.3. Crystal mounting

A mounting technique suitable for flash cooling should allow for rapid heat exchange by providing a large surface area and a minimum of extraneous material that must be cooled. The technique should also subject the crystals to little mechanical

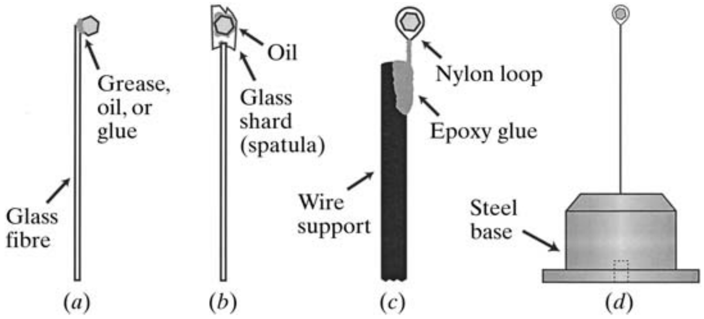


Figure 10.2.3.1
Different crystal mounts for flash cooling and cryogenic data collection. (*a*) Crystal mounted on a thin glass fibre with adhesive, grease, or oil. (*b*) Crystal placed in a hydrocarbon oil and then scooped onto a thin glass shard. (*c*) Crystal suspended in a film of aqueous solution within a nylon loop. The loop is attached to a thin (~0.25 mm diameter) wire support. (*d*) A diagram of the entire loop-mount assembly. The base is made of plain steel or a magnetic alloy and has two holes, one for the wire post and one for a locating pin, which reproducibly positions the assembly on the goniometer.

stress and should result in a relatively compact sample that can be immersed in the narrow gas stream used to maintain the temperature during data collection. The glass capillary tubes conventionally used to mount macromolecular crystals are not well suited to flash-cooling procedures since they insulate the sample, reducing cooling rates, and their bulk interferes with cryogenic equipment. A number of alternative mounting methods used for flash cooling are shown in Fig. 10.2.3.1. Crystals can be affixed directly to thin glass fibres with cement or grease (Haas & Rossmann, 1970; Dewan & Tilton, 1987), or they can be scooped up on thin glass spatulas, a procedure first used in conjunction with the oil-coating method described in Section 10.2.2 (Hope, 1988). A loop-mounting technique introduced by Teng (1990) has proven the most generally applicable, however, and has become the method of choice. Here, the crystal is held suspended in a thin film of cryosolvent formed in a small loop. The technique is quick and straightforward, remarkably gentle to the crystal, and provides a large surface area for cooling.

The loops are generally formed from nylon fibre, although glass wool is useful for larger versions because its rigidity keeps them from collapsing under the surface tension of the suspended film. Both types of fibres should have a diameter of approximately 10 µm. This small cross section reduces absorption and scattering from the material itself and also minimizes the thickness of the film in the loop. Several methods of making the loops have been described in detail (Rodgers, 1997; Garman & Schneider, 1997), and nylon loops of different sizes are available commercially. The loop is usually glued to a thin metal wire or other heat-conductive post. The ability to conduct heat rapidly is required to minimize ice formation at the point where the wire or post exits the cold gas stream of the cryostat, which occurs in some orientations of the loop assembly. This post is in turn attached to a steel base, which is used with the magnetic transfer system described below.

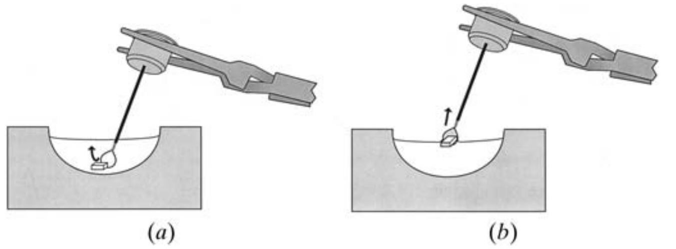

Figure 10.2.3.2
Mounting a crystal in a loop. (*a*) While viewing with a stereomicroscope, the crystal is teased to the surface of the liquid using the loop. (*b*) It is then drawn through the interface and into the loop. The sizes of the loop and crystal have been exaggerated. Reproduced with permission from Rodgers (1997). Figure 10.2.3.3
Photograph of a flash-cooled crystal mounted in a nylon loop. The wire post holding the loop is visible on the right. Reprinted from Rodgers (1994) with permission from Elsevier Science.

Crystals are placed in the loop as shown in Fig. 10.2.3.2. They can be mounted directly from the crystallization drop or after harvesting into any convenient container. Under a stereomicroscope, the crystal is teased to the surface of the solution, usually with the loop itself. Once at the surface, the crystal is carried through the interface by first resting it on the bottom of the loop and then moving the assembly vertically to pull it out of the solution. A practiced experimentalist can usually capture the crystal in the first few tries. The plane of the loop should be kept near the vertical to increase the chance of catching the crystal and to minimize the amount of liquid drawn up with it. An alternative technique is to use a small pipette to place the crystal and a drop of cryosolvent into the loop and then draw off the excess solution with filter paper. In either case, it can be difficult to form a film in

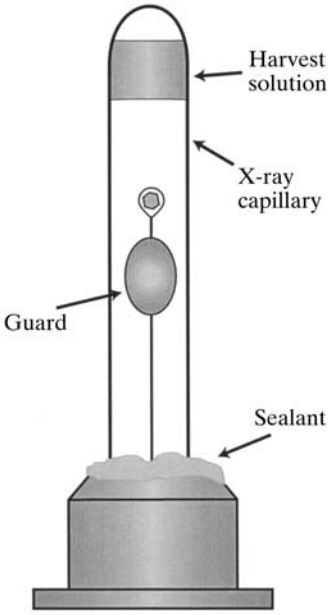

Figure 10.2.3.4
Arrangement for using the loop-mounting technique at non-cryogenic temperatures.

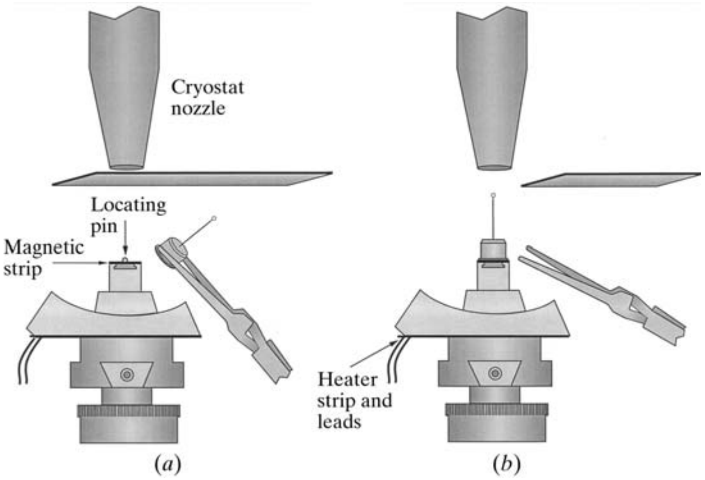

Figure 10.2.4.1
Flash cooling a crystal in the cold gas stream from a cryostat. (*a*) The cold gas from the nozzle is blocked and the loop assembly placed on the goniometer. A locating pin on the goniometer ensures reproducible positioning of the loop assembly, which is held in place by a magnetic strip. (*b*) The gas stream is then unblocked to rapidly cool the crystal. A heating element in contact with the goniometer keeps it from icing during data collection. Based on a diagram by Rodgers (1997).

the loop with solutions high in organic solvent due to the lack of surface tension. For these solutions, adding PEG up to a few per cent usually allows a stable film to form. Fig. 10.2.3.3 is a photograph of a crystal mounted in a nylon loop. If the diameter of the loop is chosen so that it just accommodates the crystal, mounting is easier and the amount of extra scattering material in the X-ray beam is reduced. Also, asymmetric crystals can then be oriented relative to the assembly by preforming the loop into the appropriate shape.

The loop-mounting technique can also be used for data collection above cryogenic temperatures by sealing the loop and pin in a large diameter (3 mm) glass or quartz X-ray capillary (Fig. 10.2.3.4). A guard composed of stiff wax or a plastic plug cemented to the pin helps to guide the capillary over the sample before sealing it to the base with high vacuum grease or a cement low in volatile solvent. Loop mounting can be less damaging for many crystals than capillary mounting, and it results in a more uniform X-ray absorption surface.

10.2.4. Flash cooling

Once mounted in the loop, the crystal must be cooled rapidly to prevent ice formation. A simple and often effective approach (see Hope, 1990; Teng, 1990) is to flash cool the sample in a cryostat gas stream (most frequently nitrogen, but also helium) right on the X-ray camera. This technique has the added advantage of leaving the crystal in position for immediate analysis and data collection. As shown in Fig. 10.2.4.1, the gas stream from the cryostat nozzle is temporarily deflected while the loop assembly is placed on the goniometer of the X-ray camera. The stream is then unblocked, allowing the cold gas to flow over the crystal. Deflecting the cold stream before placing the loop assembly eliminates the risk that the sample will cool slowly and form ice in the warmer outer layers of the gas stream. The arrangement of the cryostat nozzle shown in Fig. 10.2.4.1, with the gas stream coaxial to the loop assembly, is particularly effective. The cooling gas (usually at around 110 K for nitrogen cryostats) flows across both surfaces of the loop, maximizing the rate and evenness of cooling. Other orientations of the nozzle are frequently used, and in those cases the loop should be aligned with one edge pointing at the incoming gas. Note that a heating element, as shown in Fig. 10.2.4.1, is required to prevent icing of the goniometer with the nozzle in the coaxial position.

When handling the loop-mounted crystal before flash cooling, care must be taken to avoid drying the sample. The same characteristics that make the loop mount so effective for flash cooling, a large surface area and a small amount of surrounding solution, also promote a rapid loss of water and any other volatile component. The resulting change in solute concentration can damage the crystal or result in non-isomorphism between crystals. For this reason, every effort should be made to reduce the time required to flash cool the crystal after it is mounted. One key to avoiding delay when flash cooling in the cold stream is a rapid and reliable method of attaching the loop assembly to the goniometer. A magnetic mounting system (Fig. 10.2.4.1) developed by Rodgers (1994, 1997) is frequently used. Here, either a portion of flexible magnetic strip or solid magnet is affixed to the goniometer to hold the ferromagnetic base of the loop assembly. The base is positioned reproducibly by a small locating pin protruding from the goniometer, which mates with the centred hole in the loop base (Fig. 10.2.3.1*d*). A second pin or key can be used to specify the orientation of the loop assembly about its axis if necessary.

While flash cooling in the cold stream is convenient, an alternative method, rapidly plunging the crystal into a liquid cryogen, offers several advantages. This technique generally results in more even cooling of both sides of the loop-mounted sample, which may decrease damage due to thermal stress (Haas & Rossmann, 1970). It also reduces the time between mounting the crystal and flash cooling, and it can be used easily in any location – a cold room, for example. Another possible advantage of the liquid-cryogen method is that it produces a higher cooling rate than the cryostat gas stream, at least over much of the temperature range traversed during cooling (Walker *et al.*, 1998; Teng & Moffat, 1998). With increased cooling rates, the percentage of cryoprotectant necessary to prevent ice formation is lower, an advantage when benign cryoprotectant conditions prove difficult to find. Changes in solution dielectric or other parameters may also cause less damage. On the other hand, although cooling may be more even in a liquid cryogen, the overall increase in cooling rate could result in even greater thermal gradients, and therefore greater thermal stress, across the crystal. Systematic studies are needed to assess the effect of cooling rate on the quality of flash-cooled crystals, but in practice the liquid-cryogen technique has proven effective and is widely used.

Common cryogens for flash cooling are liquid nitrogen, propane, and, to a lesser extent, ethane and some types of Freon. (Another potentially useful cryogen, liquid helium, has not yet been explored for flash cooling macromolecular crystals.) There is some disagreement about relative cooling rates in liquid nitrogen *versus* liquid propane for samples the size of loop-mounted crystals (Walker *et al.*, 1998; Teng & Moffat, 1998), but both cryogens are known to work well for flash cooling. Since liquid nitrogen is simpler to use and safer than propane, it should be considered for initial trials with a new type of crystal. A diagram showing flash cooling with liquid nitrogen is presented in Fig. 10.2.4.2(*a*). The crystal is captured in the loop and quickly plunged into a Dewar filled with liquid nitrogen. Attaching the loop assembly to a short rod equipped with a magnetic mount allows it to be plunged deeply into the liquid nitrogen, which may increase the cooling rate by preventing the build-up of insulating

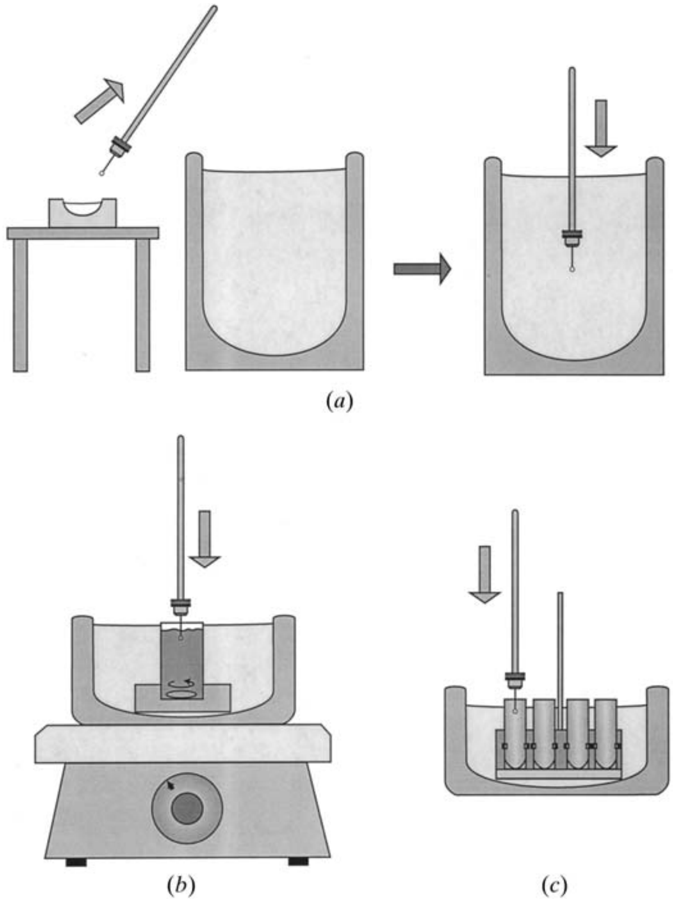

Figure 10.2.4.2
Flash cooling in a liquid cryogen. (*a*) Cooling in liquid nitrogen. The loop assembly is attached, *via* a magnet mount, to a short rod and the crystal is captured. It is then quickly plunged into a nearby Dewar of liquid nitrogen. (*b*) One method of flash cooling in a liquid cryogen such as propane. The cryogen is placed in a weighted container, which itself stands in a Dewar of liquid nitrogen. The Dewar rests on a stir plate, which mixes the liquid cryogen to ensure a uniform temperature. When the temperature of the cryogen is just above its melting point, the loop assembly is plunged into the liquid. (*c*) A variation on cooling in propane or a similar cryogen. The cryogen is placed into small plastic vials designed for cryogenic storage. Just before the cryogen freezes, the loop assembly is plunged directly into a vial. A holder for the vials allows multiple samples to be prepared sequentially.

gas around the crystal. To minimize drying of the sample during transfer, the crystal container and the Dewar are located as close as possible. If necessary, drying can be further reduced by using a portable humidifier to add moisture in the area.

Other cryogens, such as propane, can be tested if results with liquid nitrogen are not satisfactory. Two methods for flash cooling in these other cryogens are illustrated in Figs. 10.2.4.2(*b*) and (*c*). In the first (Fig. 10.2.4.2*b*), the liquid cryogen is held in a small container with a weighted base, which is placed in a Dewar of liquid nitrogen to cool the cryogen. The cryogenic liquid is mixed using a magnetic stir bar to ensure a uniform temperature throughout the sample. Since the boiling points of these cryogens are well above their melting points, it is possible in the absence of stirring to have relatively warm, and therefore less effective, cryogen near the top of the container. When a temperature probe indicates that the cryogen is just above its melting point, the crystal is mounted and plunged quickly into the liquid. A variant of this technique (Fig. 10.2.4.2*c*) calls for plunging the loop assembly directly into cryogen-filled plastic vials, which are used for low-temperature transfer and storage of the crystals (see Section 10.2.5). The cryogen is then allowed to solidify around the crystal before it is placed on the X-ray camera or stored for later use. With this technique, it is more difficult to ensure that the temperature of the cryogen is uniform throughout the container. Other mechanisms for flash cooling in liquid cryogens have been described (Hope *et al.*, 1989; Abdel-Meguid *et al.*, 1996), and devices for combining xenon derivatization with flash cooling (Soltis *et al.*, 1997) are available commercially.

10.2.5. Transfer and storage

Crystals flash cooled in a liquid cryogen must be placed for data collection in the cold gas stream of a cryostat without any substantial warming. One common transfer method (Rodgers, 1994, 1997) is shown in Fig. 10.2.5.1. Once the loop assembly has been plunged into the Dewar of liquid nitrogen, it is inserted into a small plastic vial of the type normally used for cryogenic storage, ensuring that the sample remains below the liquid surface during the operation. There is then sufficient liquid nitrogen in the vial to keep the sample cold as it is transferred to the cryostat gas stream. Again, the magnetic mounting system is used to reduce the time required for transfer. For X-ray cameras with vertical spindles, as shown in Fig. 10.2.5.1, some means of pointing the magnetic mount downward is required to prevent the nitrogen from spilling out of the vial. The goniometer illustrated has a detachable arc extension (Engel *et al.*, 1996; Litt *et al.*, 1998) that provides this capability. When the loop assembly is attached to the magnet, the vial is quickly withdrawn, exposing the crystal to the gas stream. The arc slide can then be returned to the normal position and the arc extension removed.

Another device (Mancia *et al.*, 1995) for achieving the correct transfer geometry is shown in Fig. 10.2.5.2. This ‘flipper’ mechanism can be extended to permit transfer of the crystal. The device is then rotated about the hinge to reorient the loop assembly for data collection. The

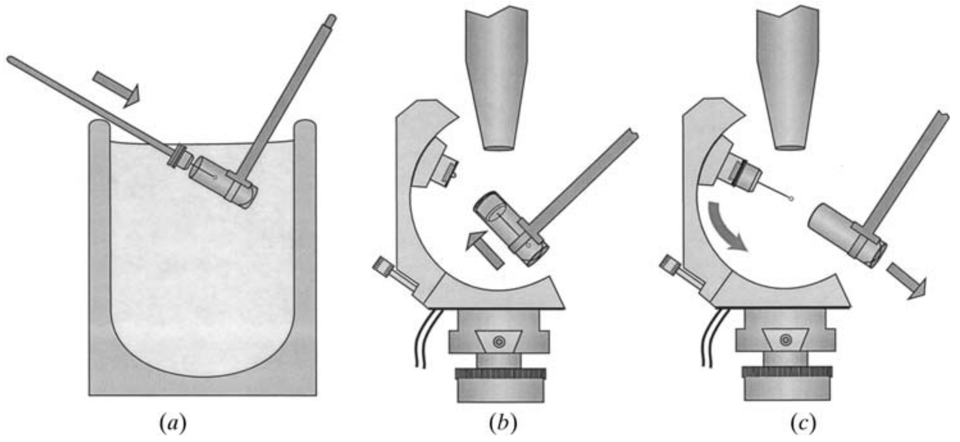

Figure 10.2.5.1
Transfer of the flash-cooled crystal and loop assembly to a goniometer using a cryovial. (*a*) The loop assembly with a flash-frozen crystal is placed in the vial, which is held by a rod-shaped tool. The operation is carried out beneath the surface of the liquid nitrogen in a Dewar. (*b*) The loop assembly is transferred to the goniometer using the magnetic mounting system. (*c*) The vial is withdrawn, exposing the crystal to the cold gas stream. With this arrangement of goniometer and cryosystem nozzle, it is necessary to use a device that allows the magnetic mount to point downward. Here, a detachable arc extension provides this ability. After crystal transfer, the arc slide can be returned to the normal position and the extension removed.

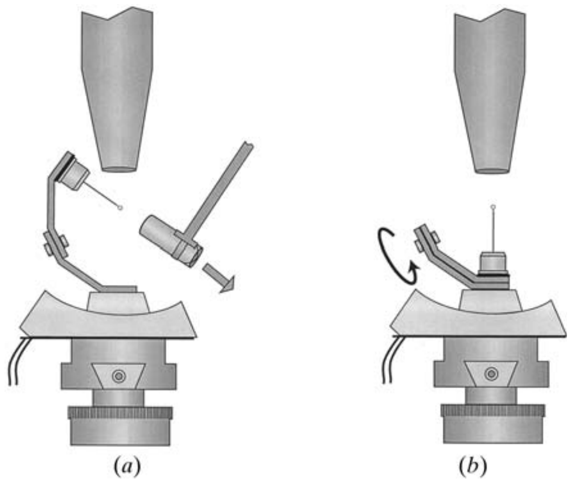

Figure 10.2.5.2
Transfer using an alternative device for achieving the correct magnetic mount orientation. (*a*) A hinged mechanism is extended to orient the magnetic mount downward, and the loop assembly is attached. (*b*) The mechanism is rotated about the hinge to place the mount in the normal orientation for data collection.

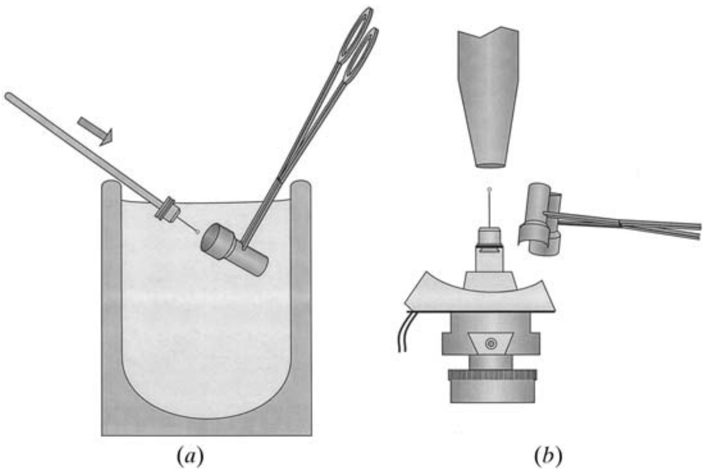

Figure 10.2.5.3
Transfer using tongs. (*a*) The crystal is inserted into a split metal cup that allows the base to be held securely. (*b*) The tongs are inverted and used to place the loop assembly on the magnetic mount. The jaws of the tongs are then opened to separate the halves of the cup, and the tongs are withdrawn.

hinge is positioned so that rotation does not translate the crystal, keeping it in the cold stream during reorientation.

When cooling in other liquid cryogens such as propane, the same cryovial transfer system is used. Flash cooling in cryovials (Fig. 10.2.4.2*c*) permits direct transfer using the magnetic mounting system. Usually, the liquid cryogen has been solidified in the vial, and it is allowed to melt at least partially before placing the crystal on the goniometer. Any remaining solid then melts and drips away (although it is often necessary to remove the last drop on the crystal with filter paper). When cooling in a larger volume of cryogen (Fig. 10.2.4.2*b*), the crystal can be 'hopped' rapidly from the cooling cryogen to the surrounding vat of liquid nitrogen. A drop of cryogen transfers with the crystal, keeping it from warming. The loop assembly can then be placed in a cryovial and transferred to the goniometer.

Another device that does not use cryovials has been introduced (Parkin & Hope, 1998) to facilitate transfer from liquid nitrogen. The device consists of a split metal cup attached to handles that allow the cup to be opened and closed. When closed, the two halves of the metal cup form a cavity that can accommodate and grasp the loop assembly. As shown in Fig. 10.2.5.3, the loop assembly is inserted after first cooling the tongs in liquid nitrogen. The thermal mass of the tongs prevents warming as the crystal is then placed on the goniometer. The tongs are opened and removed to expose the crystal to the gas stream.

Any of these transfer procedures can be reversed in order to return the loop assembly to liquid nitrogen without thawing the crystal. The assembly and cryovial can then be placed in a Dewar designed for long-term storage. Some opening should be present in the loop-assembly bases, or the cryovials should be notched, to allow free movement of liquid nitrogen. The vials are conveniently held and organized using aluminium canes, which take up to five samples and have tabs that hold the loop assemblies in place. For even more secure long-term storage, loop assemblies with threaded bases that screw into the cryovials are available.

The ability to store samples for long periods of time permits a number of crystals to be flash cooled under consistent conditions, which can be important for maintaining isomorphism, and crystals can also be stockpiled for later data collection at a synchrotron X-ray facility. In fact, crystals should be prescreened for quality in the laboratory before synchrotron data collection to make efficient use of time on the beam line. Finally, crystals that degrade in growth or harvest solutions, or that contain macromolecules in unstable or transient states, can be conveniently preserved by flash cooling and storage in liquid nitrogen.

Chapter 10.3. Radiation damage

E. F. Garman

10.3.1. Introduction

Radiation damage to macromolecular crystalline samples during the experiment is a problem inherent in using ionizing radiation to obtain diffraction patterns, and has presented a challenge to protein crystallography (MX) since the beginning of the field, often necessitating the use of many crystals to assemble a complete data set. The damage manifests itself as a decrease in diffraction intensity caused by the destruction of crystallinity. This in turn is a result of the absorption in the sample of photons in the beam by either the photoelectric effect (total absorption of the photon and ejection of an inner-shell electron) or Compton scattering (inelastic scattering of the photon which escapes, following a varying amount of energy loss to an atomic electron). At the incident energies used for MX, the former effect has a much higher cross section and dominates the absorption, accounting for over 90% of the energy deposited by the beam. Each photoelectron has enough energy to subsequently induce up to 500 ionization events, which in turn can result in the formation of radical species in the crystal. In protein crystals, the presence of anything between 20 and 80% solvent means that the radiolysis of water and other components of the solvent is an important contributor to the creation of these species. Some of the energy deposited by the beam by these processes is converted into heat and induces a temperature rise in the sample. The diffracted photons are scattered elastically and thus do not contribute to the damage.

The usage of the terms 'primary', 'secondary' and 'tertiary' damage is dependent on the context. The definitions adopted here are as follows: primary damage is the ionization of an atom due to photoelectric absorption or Compton scattering, whereas secondary damage is the formation of up to 500 lower-energy secondary electrons per primary absorption event. These have a temperature-independent continuous slowing down approximation range and induce further ionization and excitation events. The mobilities of the subsequent carriers of energy are reduced at lower temperatures, while the primary photoelectron has a temperature-independent mean track length of a few micrometres (for 12 keV photons) (O'Neill *et al.*, 2002). Tertiary damage is the effect on the crystal lattice and other mechanical consequences of the energy loss in the sample. Damage can also be classified as direct if the primary absorption event occurs at an atom in the protein molecule, or indirect if the radiation is absorbed by the surrounding solvent and the reactive species formed subsequently interact with the protein.

The universal metric against which the decay indicators of a crystal are conveniently measured is the absorbed dose, defined as the energy absorbed per unit mass of the sample (1 Gy = 1 J kg^{-1}). To calculate this requires knowledge of the sample size and composition (*i.e.* the number of each atom type in the unit cell) so that its absorption coefficients can be computed, and detailed information about the incident beam [energy, size, shape and flux (in photons s^{-1})].

The earliest investigation of radiation damage in MX was carried out at room temperature (RT) by Blake & Phillips (1962), who concluded that the damage was proportional to the absorbed dose and that the observed form of the decay with dose could be described by a first-order exponential function. They deduced that a single 8 keV X-ray photon absorbed by the crystal disrupted around 70 protein molecules, and disordered a further 90 for doses up to about 20 Mrad (0.2 MGy, since 1 Gy = 1 J kg^{-1} = 100 rad), above which the decay of the undamaged part of the crystal was faster than expected from an exponential law, due perhaps to some sort of cumulative effect. They also suggested that specific structural damage was suffered by the protein molecule; these conclusions were reached without knowledge of either the sequence or three-dimensional structure of the protein.

Despite reports from the early days of synchrotron use that crystals had longer lifetimes at higher dose rates at RT (*e.g.* Helliwell, 1988), this was only systematically investigated recently, when an inverse dose-rate effect was measured in-house between dose rates of 6 and 10 Gy s^{-1}, the higher rate giving four times the dose tolerance (*i.e.* four times the dose required to halve the total diffraction intensity, $D_{1/2}$) for chicken egg-white lysozyme crystals (Southworth-Davies *et al.*, 2007). For irradiation at a dose rate of 2800 Gy s^{-1} at a synchrotron at RT, ten times the dose tolerance has been recorded (Barker *et al.*, 2009).

Up until the 1990s, MX data were collected at RT, where the recommended practice was to monitor the intensity, I_0, of a particular reflection as the experiment proceeded, and to discard the crystal once the intensity had dropped to $0.85I_0$, or at the very worst, $0.70I_0$ if the particular crystals were in very short supply (Blundell & Johnson, 1976).

10.3.2. Cryocrystallography as a mitigation strategy

The search for strategies to reduce the rate of radiation damage in MX has resulted in the development over the last 20 years of cryocrystallographic techiques, whereby a crystal held by surface tension in a fibre, Mylar or polyimide loop is flash-cooled either into liquid nitrogen (77 K) or gaseous nitrogen at around 100 K (Garman, 1999; Garman & Schneider, 1997; see also Chapter 10.1). If the cooling is swift enough, the solvent around and within the crystal is present as amorphous solid, and does not form crystalline ice which would interfere with the diffraction and degrade the crystal order. To achieve this, cryoprotectant agents are added to the mother liquor, and optimum results can be obtained if the concentration of cryoprotectant results in equal shrinkage of the solvent channels and unit cell when the crystal is cooled (Juers & Matthews, 2001). At 100 K, nearly all the radical species in the crystal are immobilized and so, although the primary radiation damage is unchanged and the resulting electrons of higher energy, and perhaps holes, are still mobile, other radicals that are subsequently formed (*e.g.* hydroxyl and other oxygen-centred radicals) have significantly lower mobility and thus their potential to inflict damage is quenched.

Widespread use of these techniques seemed to overcome most radiation-damage problems, since cryocooling resulted in a vastly extended dose tolerance (around a factor of 70; Nave & Garman, 2005) for most macromolecular crystals. However, with the advent of more intense second- and third-generation synchrotron

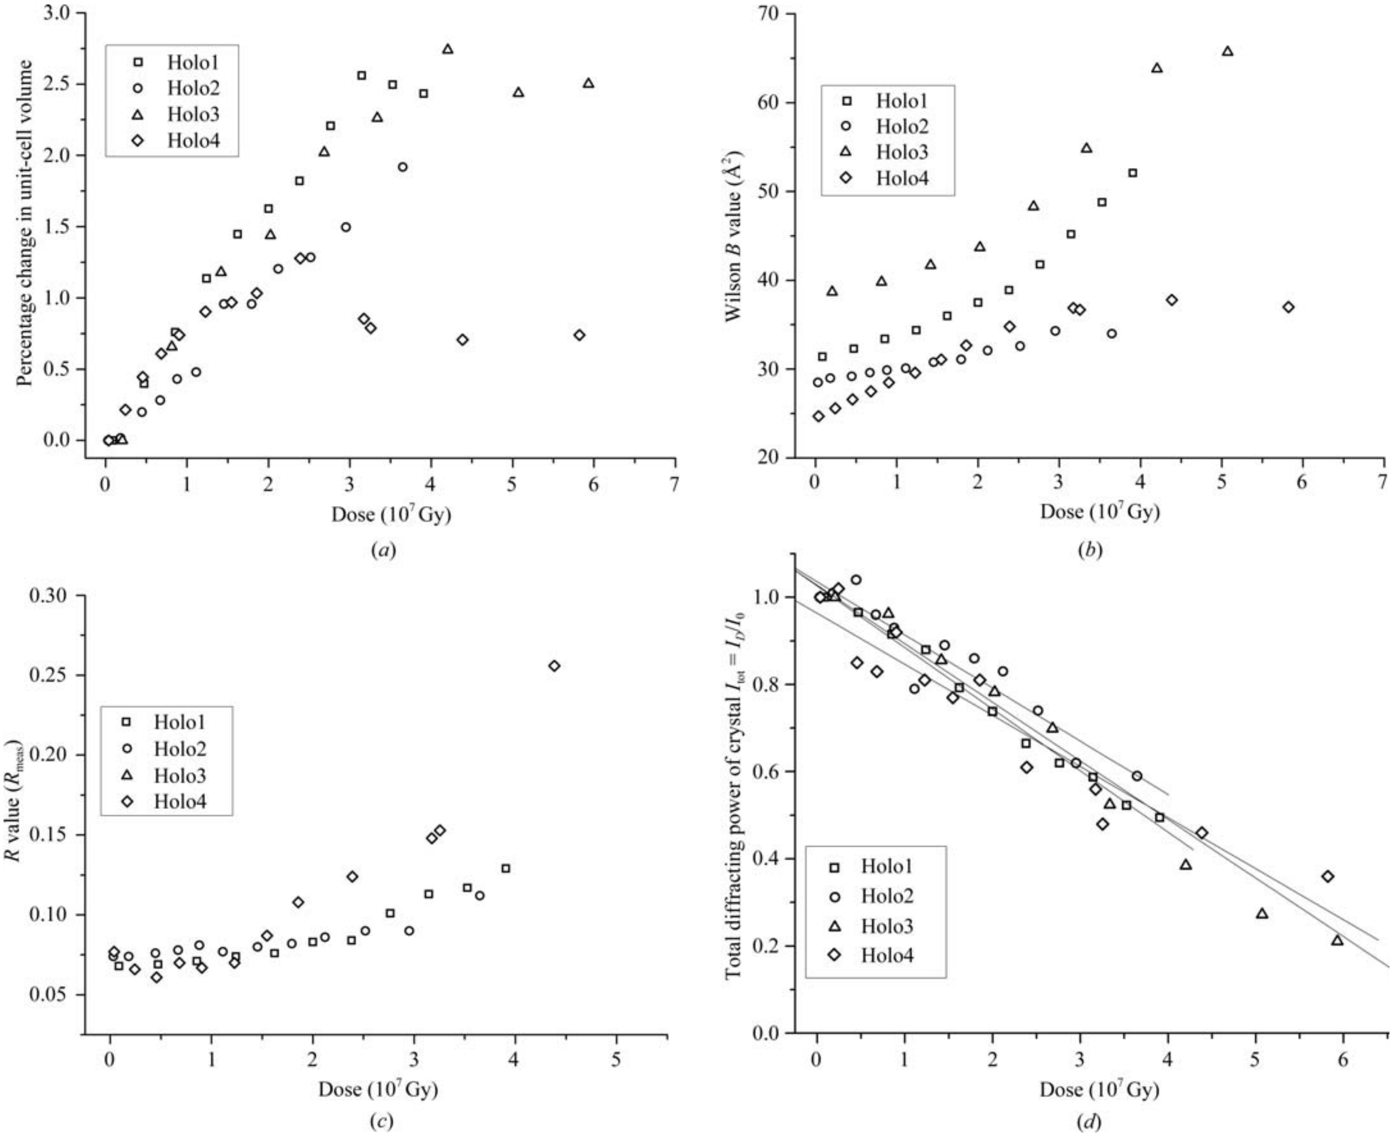

Figure 10.3.3.1

Global radiation-damage indicators as a function of dose for four holoferritin crystals (Owen *et al.*, 2006): (*a*) unit-cell volume, (*b*) Wilson *B* factor, (*c*) $R_{\rm merge}$ and (*d*) I(mean)/I_0(mean).

X-ray beams in the 1990s, observations of radiation damage to samples, even when held at 100 K, became common.

10.3.3. Characteristics of radiation damage at cryotemperatures

Systematic studies on this phenomenon have identified two separate indicators of damage as a function of dose: global (Fig. 10.3.3.1) and specific (Fig. 10.3.3.2) damage. The former results in a loss of the measured reflection intensities particularly at high resolution, expansion of the unit-cell volume, increasing values of the measure of the internal consistency of the data which quantifies the difference between reflection intensities that should ideally be the same ($R_{\rm merge}$), an increase in both the scaling *B* factors for the data and the atomic *B* factors of the refined structure, rotation of the molecule within the unit cell, and often (but not always) an increase in mosaicity. Visible changes in the samples are also observed (see Fig. 10.3.3.3). On warming following irradiation, bubbles of gas, thought to be hydrogen or CO_2, are emitted. Of more direct relevance to the biological interpretation of structures, specific structural damage to particular covalent bonds is observed to occur in a reproducible order in many proteins: first disulfide bridges are broken, then glutamates and aspartates are decarboxylated, tyrosine residues lose their hydroxyl group, and subsequently the carbon–sulfur bonds in methionines are cleaved (Burmeister, 2000; Ravelli & McSweeney, 2000; Weik *et al.*, 2000). Enzyme mechanisms can involve susceptible residues, so special care is required when interpreting structures that may have been modified by X-ray damage during the data collection. Metalloproteins are particularly vulnerable to partial reduction during the diffraction experiment and may not be in their native state by the end of the data collection (Carugo & Djinović Carugo, 2005). This specific damage often occurs well before there is any obvious degradation of the diffraction pattern.

In addition, as the diffraction experiment proceeds, the growing specific structural damage combined with the gradual increase in unit-cell volume and possible movement of the protein molecule within the unit cell induces creeping non-isomorphism on three simultaneous fronts. MAD (multiple-wavelength anomalous dispersion) structure solution thus becomes problematic, since by the time the third wavelength is collected, the cell and atomic structure can have changed such that the reflection intensities are significantly altered and this effect can obscure the anomalous signal required for structure solution.

The global effects at 100 K are thought to be dose-rate independent up to the flux densities currently used (10^{15} photons s^{-1} mm^{-2}) (Sliz *et al.*, 2003). Another study con-

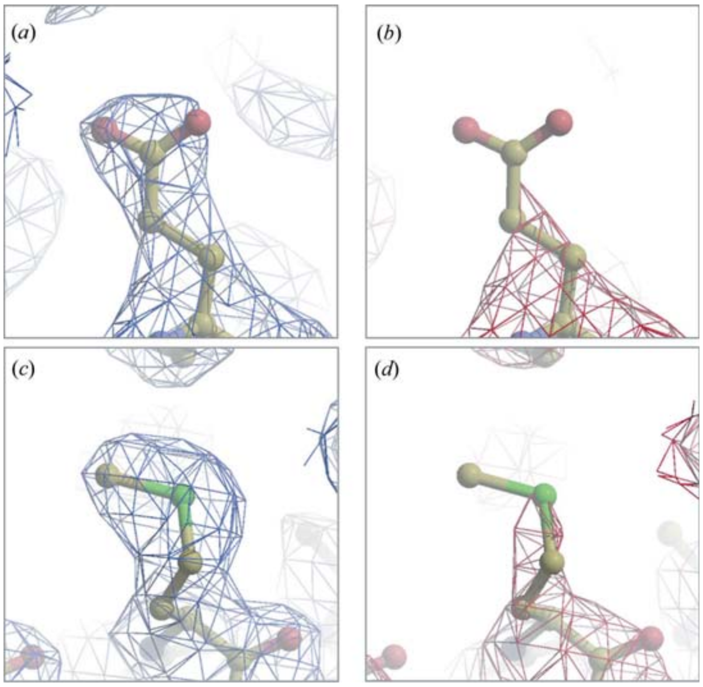

Figure 10.3.3.2
Specific structural damage inflicted on a cryocooled crystal of apoferritin during sequential data sets collected at ID14-4, ESRF: (*a*) $2F_o - F_c$ map of Glu63 contoured at 0.2 e Å^{-3} after a dose of 2.5 MGy and (*b*) after 50 MGy. (*c*) $2F_o - F_c$ map of Met96 contoured at 0.2 e Å^{-3} after a dose of 2.5 MGy and (*d*) after 50 MGy, showing loss of electron density around the disordered atoms (Garman & Owen, 2006).

curred with this finding, but indicated that there could be a second-order dose-rate effect based upon analysis of difference electron-density maps, specific damage being slightly more severe at higher dose rates (Leiros *et al.*, 2006). Conversely, however, Owen *et al.* (2006) reported a small (10%) reduction in $D_{1/2}$ for a dose-rate increase from 0.4×10^4 to 4.0×10^4 Gy s^{-1}.

Radiation damage thus ultimately results in lower-resolution structures, failed MAD structure solutions and sometimes the inaccurate interpretation of biological results if no control experiments are carried out to account for radiation-damage artefacts (Ravelli & Garman, 2006). It is thus an issue to be taken seriously by the structural biologist.

10.3.4. Understanding radiation damage

In order to monitor and understand radiation damage, it is vital to have reliable metrics to allow systematic and comparative studies. Several different global measures extracted from the data are currently being utilized: $[I/\sigma(I)]/[I_0/\sigma(I_0)]$, where I_0 is the initial intensity of a data set or of a set of reflections, $I(\text{mean})/I_0(\text{mean})$, the 'decay R factor', R_d, a pairwise R factor between identical and symmetry-related reflections occurring on different diffraction images, which is plotted against the difference in dose, ΔD, between the images in which the reflections were observed (Diederichs, 2006), isotropic B factor ($B_{\rm rel}$), which was found to be linearly dependent on dose, and a coefficient of sensitivity ($S_{\rm AD} = \Delta B_{\rm rel}/\Delta D 8\pi^2$, where $\Delta B_{\rm rel}/8\pi^2$ is the change in relative isotropic B factor and ΔD is the change in dose). The latter coefficient relates the increase in mean-squared atomic displacements to the dose, and was found to be a robust measure for radiation damage (Kmetko *et al.*, 2006). Unit-cell volume is not used, since it has been found to be an unreliable indicator (Murray & Garman, 2002; Ravelli *et al.*, 2002). Some of the above metrics are more appropriate than others for use in particular circumstances, *e.g.* if maximizing the resolution, trying to minimize radiation-damage-induced artefacts, or carrying out SAD (single-wavelength anomalous dispersion)/MAD structure solution. Care must be exercised in the calculation of electron-density maps extracted from sequential data sets, since the maps can be biased by the refinement, and so usually the phases from the refined structure obtained from the first data set are used for the map calculations of structures from the subsequent data sets.

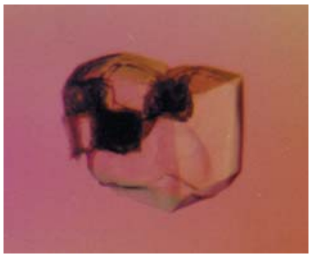

Figure 10.3.3.3
Photograph of a 400 µm neuraminidase crystal (subtype N9 from avian influenza isolated from a Noddy Tern) that has been irradiated on ID14-4 at the ESRF at 100 K and then allowed to warm to room temperature. The three black marks are from the 100 × 100 µm beam, the discolouration being an indication of radiation damage.

There is postulated to be a universal 'dose limit' for biological samples, beyond which they cannot be expected to survive intact and are destroyed by the energy deposited in them. From analogy with observations in electron microscopy (for 100 keV electrons), a dose limit of $D_{1/2} = 20$ MGy for a cryocooled (77 K) protein crystal was calculated by Henderson (1990). More recently Owen *et al.* (2006) have published an experimental study of the dose limit for cryocooled (100 K) protein crystals, in which it was found that the total intensity of diffraction had a linear dependence on absorbed dose (as opposed to the exponential dependence at room temperature). The dose required to halve the total intensity of the diffraction pattern was 43 MGy, but an upper limit of 30 MGy was suggested ($I = 0.7I_0$), beyond which point the biological information obtained from the experiment might be compromised. Coincidentally, this is the value of intensity loss previously recommended as the absolute maximum allowable for individual reflections during room-temperature data collection (Blundell & Johnson, 1976).

For systematic radiation-damage experiments and also for the 30 MGy experimental dose limit to be a useful predictive experimental tool, the dose absorbed by the crystal must be calculated. This can be conveniently computed for MX using the program *RADDOSE* (Murray *et al.*, 2004; Paithankar *et al.*, 2009), which requires information on the crystal, protein, cell and m*M* concentration of mother liquor, as well as the beam characteristics, and the duration and number of the exposures. The output gives the time available before the experimental dose limit is reached and the predicted temperature rise in the crystal using a simple isothermal 'lumped model'. Version 3 of *RADDOSE* takes into account the possible escape from the sample of fluorescence X-rays from the decay of excited atoms (only significant for atoms with atomic number greater than 20) following photoelectron emission, and also the energy deposited in the crystal by Compton scattering (non-negligible only above incident X-ray energies of 20 keV). If the crystal is bigger than the beam the program overestimates the dose, since the rotation of the crystal during the experiment is not taken into account and new un-irradiated material will be brought in with time, thus decreasing the dose.

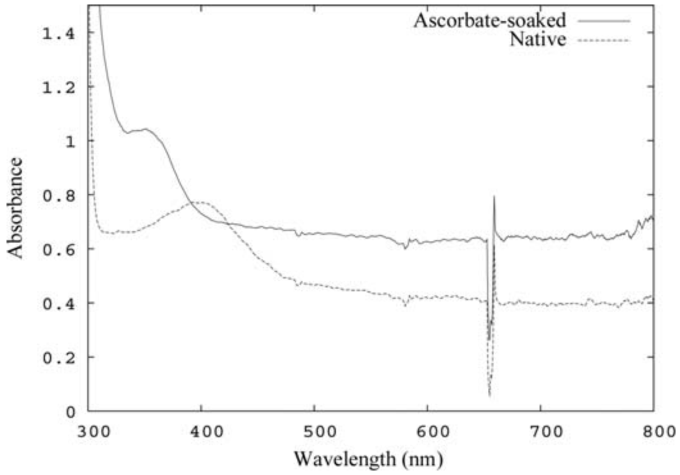

Figure 10.3.4.1
Microspectrophotometer absorption spectra of native and ascorbate-soaked hen egg-white lysozyme crystals at 100 K, showing the disulfide radical 400 nm peak formed on irradiation by a synchrotron X-ray beam, and the suppression of this peak on the addition of ascorbate, which has an absorption peak at 350 nm (Murray & Garman, 2002).

To account for the observed damage effects at 100 K, information must be gleaned from the radiation chemistry literature. Several analyses of the mobility of the various species formed upon X-ray exposure have been carried out and they help to explain the effectiveness of cryocooling for MX. Protons are only known to become mobile in amorphous ice above ~115 K (Fisher & Devlin, 1995) and although $^{\bullet}$OH radicals are trapped at 77 K in an aqueous glass of 6 *M* CsF (Becker *et al.*, 1994) and are inferred to be trapped in ice at 100 K but are thought to be mobile above 130 K and thus able to recombine (Symons, 1999), they have also been reported to be mobile at 77 K in a glass of DNA (Lange & Httermann, 1995). According to electron spin resonance measurements (Jones *et al.*, 1987), at 77 K positive holes in proteins are rapidly trapped, forming amido radicals on the protein backbone chain, whereas the electrons produced by inelastic interactions have significant mobility. Rao *et al.* (1983) showed that electrons added to proteins at 77 K are able to move efficiently until they encounter S—S bonds, where they are trapped.

Complementary methods are increasingly being employed for the observation of radiation damage in MX and specially designed instruments are being constructed on synchrotron beamlines to facilitate measurements performed simultaneously with X-ray diffraction, including UV–vis microspectroscopy (McGeehan *et al.*, 2009), UV–vis fluorescence, X-ray spectroscopy (Yano *et al.*, 2005) and Raman spectroscopy (Owen *et al.*, 2009). Optical peaks at 400 nm and between 550 and 600 nm are signatures of the formation of the disulfide radical anion, $RSSR^{\bullet}$ (Fig. 10.3.4.1) (Weik *et al.*, 2002), and the hydrated electron, respectively. The reduction of metal sites by the X-ray beam can also be observed online from their change in optical absorption (Hough *et al.*, 2008).

10.3.5. Mitigating and correcting for radiation damage

Various experimental parameters have been investigated to find ways of reducing the rate of radiation damage at cryotemperatures, including further reducing the temperature, changing the incident wavelength and adding radical scavengers.

Various studies have investigated the rate of global and specific damage infliction with temperature variation, and there is as yet no consensus on this issue. At 40 K, global indicators improved little (Teng & Moffat, 2002), but a study at 8 K found a 25% increase in dose tolerance (Chinte *et al.*, 2007). Another investigation, which also monitored global indicators, reported no improvement for insulin crystal dose tolerance at 15 K, but a 23% improvement for holoferritin, which has a large iron core (Meents *et al.*, 2007). However, significant protection against specific damage (a factor of 30 at 40 K compared to 110 K) has been observed as monitored by the intensity of the photoreduced peak in the X-ray absorption spectrum at the iron *K* edge on an iron-containing metalloprotein (Corbett *et al.*, 2007).

At current fluxes (4×10^{14} photons s^{-1} mm^{-2}), heating of the sample by the beam is predicted to be no more than 15 K (Mhaisekar *et al.*, 2005), so nitrogen cooling to 100 K is adequate to avoid the movement of species other than the already mobile electrons and perhaps positive holes (Jones *et al.*, 1987).

Despite much anecdotal evidence that longer-wavelength incident radiation causes swifter damage than shorter-wavelength incident radiation, systematic studies of this relationship (Shimizu *et al.*, 2007; Weiss *et al.*, 2005) have shown no detectable change in the damage rate with dose over the range 6.2 keV (2 Å) to 33 keV (0.275 Å). Although the absorption is higher at longer wavelengths, the probability of diffraction is also higher, and the ratio of scattering to dose is not predicted to change by more than 20% for a typical protein crystal (no heavy atoms) over the range of energies currently used in MX (7–20 keV).

Two scavengers have been tested at RT in the past (styrene and polyethylene glycol), but neither was found to be very effective and they have not been widely utilized. However, recently, 0.5 *M* ascorbate and 0.5 *M* 1,4-benzoquinone were reported to give an increase by factors of two and nine, respectively, in $D_{1/2}$ at RT. Most interestingly, for both scavengers, the dose dependence of the intensity decay was modified to a linear relationship rather than exhibiting the exponential intensity decay of the native crystal (Barker *et al.*, 2009). The decay of the total diffraction intensity observed at 100 K is predominantly linear (Fig. 10.3.3.1), and this result indicates that the radiation chemistry of the degradation of the crystalline order has been modified by the scavengers in a similar way as it is by temperature if cryocooled.

At 100 K, several scavengers have now been tested: styrene was reported to be ineffective but ascorbate reduced both global and specific damage (Murray & Garman, 2002). Nicotinic acid and 5,5′-dithiobis-2-nitrobenzoic acid (DTNB) have been found to be effective (Kauffmann *et al.*, 2006). A large number of potential scavengers were screened using an online microspectrophotometer (McGeehan *et al.*, 2009) for their ability to quench the formation of the disulfide radical anion 400 nm peak, and only ascorbate, 1,4-benzoquinone and TEMP (2,2,6,6,-tetramethyl-4-piperidone) eradicated it (Southworth-Davies & Garman, 2007). Thus, from the research carried out so far at 100 K, it seems that scavengers deserve further study but are not going to give a large improvement in dose tolerance and do not seem to be as potentially effective as they are at RT.

In addition to these experimental strategies, software development is underway to correct data for radiation damage ‘after the event’. These methods include zero-dose extrapolation, which uses multiple measurements of the same reflection to estimate its probable intensity at the beginning of the experiment (Blake & Phillips, 1962; Diederichs *et al.*, 2003), and the occupancy refinement of heavy-atom sites as a function of dose (Schiltz *et al.*, 2004).

10.3.6. Using radiation damage

The specific structural damage inflicted by radiation can be utilized for phasing, for example RIP, radiation-damage-induced phasing (Ravelli *et al.*, 2003), whereby a low-dose data collection (little specific damage) is followed by a 'burn', inflicted either by the X-ray beam or by a UV laser (Nanao & Ravelli, 2006), and then another low-dose data collection (disulfides broken and the relevant sulfur atoms thus disordered). This method has also been combined with anomalous scattering (RIPAS) (Zwart *et al.*, 2004).

Radiation damage can also be used to elucidate biological function and mechanism, and there are increasing numbers of such reports. For instance, the 'back-door' escape route of product clearance in acetylcholinesterase was identified using the X-ray beam to radiocleave a non-hydrolysable substrate analogue bound in the enzymatic site and collecting diffraction data sets at 100 and 150 K, the dynamic changes involved becoming visible at the higher temperature (Colletier *et al.*, 2008).

Other work exploiting radiation damage includes an inventive data-collection regime on a series of crystals utilizing the reduction of metal centres by the X-ray beam to track the resulting conformational changes, which shed light on the catalytic pathway of horseradish peroxidase (Berglund *et al.*, 2002).

10.3.7. Open questions

There are still many areas where systematic investigations are required to improve our understanding of the radiation chemistry within an irradiated protein crystal held at either room temperature or at various cryotemperatures, so that better strategies for minimizing damage can be developed. For instance, regarding specific damage, the varying susceptibility of the same type of residue within a protein is not yet understood: there appears to be no correlation with solvent accessibility (Fioravanti *et al.*, 2007). On the data-collection side, there is as yet no compelling evidence to warrant the routine use of helium cryostats (and the associated expense) apart from the case of metalloproteins, and there exists an urgent need to establish the best experimental strategies and optimum crystal sizes to allow the most advantageous use of newly available microbeams at synchrotrons.

The most useful contribution to be made by MX radiation-damage research is in identifying concrete experimental protocols for everyday use on synchrotron beamlines so that researchers can ensure that they obtain the maximum possible amount of high-quality data from their crystals. This would firstly facilitate structure solution, and secondly avoid compromising the biological information extracted from the structure once obtained.

PART 11. DATA PROCESSING

Chapter 11.1. Automatic indexing of oscillation images

M. G. Rossmann

11.1.1. Introduction

Auto-indexing routines have been used extensively for initiating diffraction data collection with a single-point-detector device (Sparks, 1976, 1982). These methods depend upon the precise knowledge of the reciprocal-lattice vectors for a few selected reflections. Greater difficulty has been encountered for automatic indexing of oscillation images recorded on two-dimensional detectors using randomly oriented crystals, as is frequently the case for macromolecular crystal samples. In the past, the practice was to orient crystals relative to the camera axes with an accuracy of at least 1°. In this case, the indexing procedure required only refinement of the crystal orientation matrix (Wonacott, 1977; Rossmann, 1979). The 'American method' (Rossmann & Erickson, 1983), where crystals are oriented more or less randomly, is currently used because of the need for optimizing available synchrotron time and because of the deterioration in radiation-sensitive crystals during the setting process.

A variety of techniques were suggested to determine the crystal orientation, some of which required initial knowledge of the cell dimensions (Vriend & Rossmann, 1987; Kabsch, 1988), while more advanced techniques (Kim, 1989; Higashi, 1990; Kabsch, 1993) determined both cell dimensions and crystal orientation. All these methods start with the determination of the reciprocal-lattice vectors assuming that the oscillation photographs are 'stills'. The methods of Higashi and Kabsch, as well as, in part, Kim's, analyse the distribution of the difference vectors generated from the reciprocal-lattice vectors. The most frequent difference vectors are taken as the basis vectors defining the reciprocal-lattice unit cell and its orientation. In addition, Kim's technique requires the input of the orientation of a likely zone-axis direction onto which the reciprocal-lattice vectors are then projected. The projections will have a periodicity distribution consistent with the reciprocal-lattice planes perpendicular to the zone axis. Duisenberg (1992) used a similar approach for single-point-detector data, although he did not rely on prior knowledge of the zone-axis direction. Instead, he defined possible zone axes as being perpendicular to a reciprocal-lattice plane by combining three, suitably chosen, reciprocal-lattice points.

None of the above techniques were entirely satisfactory as they sometimes failed to find a suitable crystal orientation matrix. A major advance was made in the program *DENZO*, a part of the *HKL* package (Otwinowski & Minor, 1997), which not only has a robust indexing procedure but also has a useful graphical interface. Unfortunately, the indexing technique used in the procedure has never been described, except for a few hints in the manual on the use of an FFT (fast Fourier transform). Indeed, Bricogne (1986) suggested that a three-dimensional Fourier transformation might be a powerful indexing tool, and Strouse (1996) developed such a procedure for single-point-detector data. However, for large unit cells this procedure requires an excessive amount of memory and time (Campbell, 1997).

11.1.2. The crystal orientation matrix

The position $\mathbf{x}\ (x, y, z)$ of a reciprocal-lattice point can be given as

$$\mathbf{x} = [\Phi][A]\mathbf{h}. \qquad (11.1.2.1)$$

The matrix $[\Phi]$ is a rotation matrix around the camera's spindle axis for a rotation of φ. The vector $\mathbf{h}$ represents the Miller indices (h, k, l) and $[A]$ defines the reciprocal unit-cell dimensions and the orientation of the crystal lattice with respect to the camera axes when $\varphi = 0$. Thus,

$$[A] = \begin{pmatrix} a_x^* & b_x^* & c_x^* \\ a_y^* & b_y^* & c_y^* \\ a_z^* & b_z^* & c_z^* \end{pmatrix}, \qquad (11.1.2.2)$$

where a_x^*, a_y^* and a_z^* are the components of the crystal $\mathbf{a}^*$ axis with respect to the orthogonal camera axes. When an oscillation image is recorded, the position of a reciprocal-lattice point is moved from $\mathbf{x}_1$ to $\mathbf{x}_2$, corresponding to a rotation of the crystal from φ_1 to φ_2. The recorded position of the reflection on the detector corresponds to the point $\mathbf{x}$ when it is on the Ewald sphere somewhere between $\mathbf{x}_1$ and $\mathbf{x}_2$. The actual value of φ at which this crossing occurs cannot be retrieved from the oscillation image. We shall therefore assume here, as is the case in all other procedures, that $[\Phi][A]$ defines the crystal orientation in the centre of the oscillation range. Defining the camera axes as in Rossmann (1979), it is easy to show that a reflection recorded at the position (X, Y) on a flat detector normal to the X-ray beam, at a distance D from the crystal, corresponds to

$$\begin{aligned} x &= \frac{X}{\lambda(X^2 + Y^2 + D^2)^{1/2}} \\ y &= \frac{Y}{\lambda(X^2 + Y^2 + D^2)^{1/2}} \\ z &= \frac{D}{\lambda(X^2 + Y^2 + D^2)^{1/2}}, \end{aligned} \qquad (11.1.2.3)$$

where λ is the X-ray wavelength.

If an approximate $[A]$ matrix is available, the Miller indices of an observed peak at (X, Y) can be roughly determined using (11.1.2.3) and (11.1.2.1), where

$$\mathbf{h} = [A]^{-1}[\Phi]^{-1}\mathbf{x}, \qquad (11.1.2.4)$$

with the error being dependent upon the width of the oscillation range, the error in the detector parameters and errors in determining the coordinates of the centres of the recorded reflections.

11.1.3. Fourier analysis of the reciprocal-lattice vector distribution when projected onto a chosen direction

If the members of a set of reciprocal-lattice planes perpendicular to a chosen direction are well separated, then the projections of the reciprocal-lattice vectors onto this direction will have an easily recognizable periodic distribution (Fig. 11.1.3.1). Unlike the procedure of Kim (1989), which requires the input of a likely

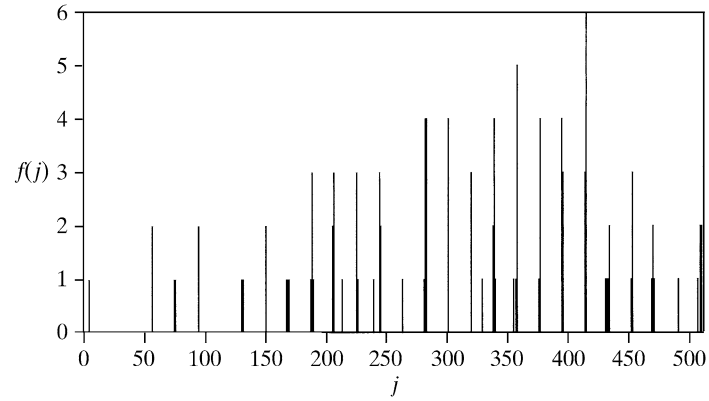

Figure 11.1.3.1
Frequency distribution of the projected reciprocal-lattice vectors for a suitably chosen direction of a diffraction pattern from a fibritin crystal (Tao *et al.*, 1997). Reproduced with permission from Steller *et al.* (1997).

zone-axis direction, the present procedure tests all possible directions and analyses the frequency distribution of the projected reciprocal-lattice vectors in each case. Also, unlike the procedure of Kim, the periodicity is determined using an FFT.

Let **t** represent a dimensionless unit vector of a chosen direction. Then, the projection p of a reciprocal-lattice point **x** onto the chosen vector **t** is given by

$$p = \mathbf{x} \cdot \mathbf{t}. \qquad (11.1.3.1)$$

To apply a discrete FFT algorithm, all such projections of the reciprocal-lattice points onto the chosen direction **t** are sampled in small increments of p. For the given direction, the values of the projections are in a range between the endpoints $p_{\min}$ and $p_{\max}$. If the maximum real cell dimension is assumed to be $a_{\max}$, then the maximum number of reciprocal-lattice planes between the observed limits of p is $(p_{\max} - p_{\min})/(1/a_{\max})$. Hence, the number of useful grid points along the direction **t** should be

$$m = (p_{\max} - p_{\min}) n a_{\max}, \qquad (11.1.3.2)$$

where n represents the number of grid points between successive reciprocal-lattice planes and is normally set to 5. Then, the frequency $f(p)$ in the range $p < \mathbf{x} \cdot \mathbf{t} < p + \Delta p$ can be given as $f(p)\Delta p = f(j)$, where j is the closest integer to $(p - p_{\min})/\Delta p$ and $\Delta p = n a_{\max}$. Thus, the discrete Fourier transform of this frequency distribution will be given by the summation

$$F(k) = \sum_{j=0}^{m} f(j) \exp(2\pi i k j). \qquad (11.1.3.3)$$

The transform is then calculated using a fast Fourier algorithm for all integer values between 0 and $m/2$ (Fig. 11.1.3.2). The Fourier coefficients that best represent the periodicity of the frequency distribution will be large. The largest coefficient will occur at $k = 0$ and correspond to the number of vectors used in establishing the frequency distribution. The next set of large coefficients will correspond to the periodicity that represents every reciprocal-lattice plane. The ratio of this maximum to $F(0)$ will be a measure of the tightness of the frequency distribution around each lattice plane. Subsequent maxima will be due to periodicities spanning every second, third *etc.* frequency maximum and will thus be progressively smaller (Fig. 11.1.3.2). The largest $F(k)$ (when $k = l$), other than $F(0)$, will, therefore, correspond to an interval of d^* between reciprocal-lattice planes in the direction of **t** where $d^* = l/(na_{\max})$.

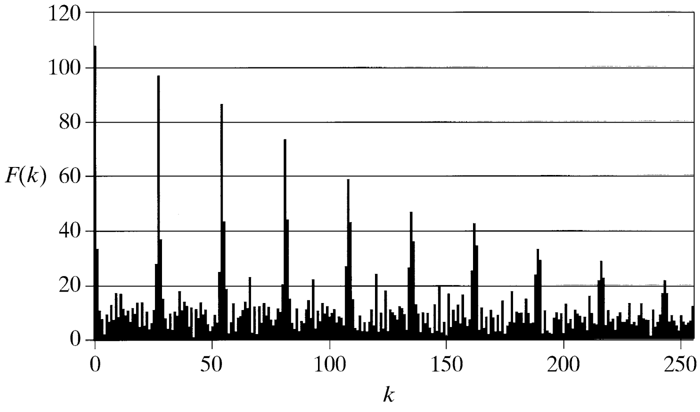

Figure 11.1.3.2
Fourier analysis of the distribution shown in Fig. 11.1.3.1. The first maximum, other than $F(0)$, is at $k = 27$, corresponding to $(1/d^*) = 41.9$ Å and a value of $F(27) = 97.0$. Reproduced with permission from Steller *et al.* (1997).

11.1.4. Exploring all possible directions to find a good set of basis vectors

The polar coordinates ψ, φ will be used to define the direction **t**, where ψ defines the angle between the X-ray beam and the chosen direction **t**. The Fourier analysis is performed for each direction **t** in the range $0 < \psi \leq \pi/2, 0 < \varphi \leq 2\pi$. A suitable angular increment in ψ was determined empirically to be about 0.03 rad (1.7°). For each value of ψ, the increment in φ is taken to be the closest integral value to $(2\pi \sin \psi)/0.03$. This procedure results in ~7300 separate, roughly equally spaced, directions.

For each direction **t**, the distribution of the corresponding $F(k)$ coefficients is surveyed to locate the largest local maximum at $k = l$. The ψ and φ values associated with the 30 largest maxima are selected for refinement by a local search procedure to obtain an accuracy of 10^{-4} rad (~0.006°). If the initial angular increment (0.03 rad) used for the hemisphere search was reduced, then it would not be necessary to refine quite as many local maxima. However, to increase the efficiency of the search procedure, the ratio of angular increments to the number of refined positions was chosen to minimize the total computing time. The $F(l)$ values of the refined positions are then sorted by size. Directions are chosen from these vectors to give a linearly independent set of three basis vectors of a primitive real-space unit cell. These are then converted to the basis vectors of the reciprocal cell. The components of the three reciprocal-cell axes along the three camera axes are the nine components of the crystal orientation matrix $[A]$ (11.1.2.2).

The final step in the selection of the best $[A]$ matrix is to choose various nonlinear combinations of the refined vectors that have the biggest $F(l)$ values. That set of three vectors which gives the best indexing results is then chosen to represent the crystal orientation matrix $[A]$. A useful criterion is to determine the nonintegral Miller indices h' from (11.1.2.4) using the $[A]$ matrix and the known reciprocal-lattice vectors **x**. Any reflection for which any component $|\mathbf{h} - \mathbf{h}'|$ is bigger than, say, 0.2 is rejected. The best $[A]$ matrix is chosen as the one with the least number of rejections. In most cases, the best combination corresponds to taking the three largest $F(l)$ values.

The program goes on to determine a reduced cell from the cell obtained by the above indexing procedure (Kim, 1989). The reduced cell is then analysed in terms of the 44 lattice characters (Burzlaff *et al.*, 2005; Kabsch, 1993) in order to evaluate the most likely Bravais lattice and crystal system.

11.1.5. The program

The auto-indexing program has been written in C and implemented on an SGI O^2 workstation. It is a component of the general data-processing system (*DPS*). The auto-indexing component of *DPS* is available over the web, including the source code. The run-time for auto-indexing is sufficiently short for the procedure to be run interactively. The program described here is now included in the *MOSFLM* data-processing package (Leslie, 1992).

This short article is adapted from a fuller description of the auto-indexing procedure (Steller *et al.*, 1997). I thank Cheryl Towell and Sharon Wilder for help in the preparation of this manuscript. The work was supported by a grant from the National Science Foundation to MGR. Ingo Steller, who wrote and developed the program, was supported by a Deutsche Forschungsgemeinschaft postdoctoral fellowship.

Chapter 11.2. Integration of macromolecular diffraction data

A. G. W. Leslie

11.2.1. Introduction

Data integration refers to the process of obtaining estimates of diffracted intensities (and their standard deviations) from the raw images recorded by an X-ray detector. As two-dimensional (2D) area detectors are almost universally used to collect macromolecular diffraction data, only this type of detector will be considered in the following analysis.

When collecting data with a 2D area detector, a decision has to be taken about the magnitude of the angular rotation of the crystal during the recording of each image. Two distinct modes of operation are possible: the rotation per image can be comparable to, or greater than, the angular reflection range of a typical reflection (coarse φ slicing), or it can be much less than the reflection width (fine φ slicing). The latter approach allows the use of three-dimensional profile fitting and, providing that the detector is relatively noise-free, improves the quality of the resulting data by minimizing the contribution of the X-ray background to the total measured intensity. However, there are significant overheads associated with recording, storing and processing the relatively large number of images that are required. Three-dimensional profile fitting is described in Chapter 11.3 and will not be discussed here.

11.2.2. Prerequisites for accurate integration

11.2.2.1. Crystal parameters

Only the integration procedure itself will be described in detail in this article. However, in order to obtain the highest quality data possible from a given set of images, there are a number of parameters that need to be determined in advance of, or during, the integration. The most important of these are the unit-cell parameters , which should be determined to an accuracy of a few parts in a thousand (or better). Post-refinement procedures (Winkler *et al.*, 1979; Rossmann *et al.*, 1979), which make use of the estimated φ centroids of observed spots rather than their detector coordinates, generally provide more accurate estimates than methods based on the spot positions. This is because spot positions are affected by residual spatial distortions (after applying appropriate corrections) and the cell parameters are correlated with the crystal-to-detector distance, which is not always accurately known. For either method, it is necessary to include data from widely separated regions of reciprocal space (ideally φ values 90° apart) in order to determine all unit-cell parameters accurately. This is particularly important for lower-symmetry space groups.

The crystal orientation also needs to be known to an accuracy that corresponds to a few per cent of the reflection width. For crystals with low mosaicity (*e.g.* 0.1°) this corresponds to a hundredth of a degree or better. Fortunately, it is a feature of post refinement that the error in determining the orientation is typically a few per cent of the reflection width, and so this condition can generally be met. It is important to allow for movement of the crystal by continuously updating the crystal orientation during integration. This is even true when using cryo-cooled crystals, as the magnetic couplings that attach the pin (holding the crystal) to the goniometer head are not strong enough to prevent small movements, particularly with the high angular rotation rates employed on intense synchrotron beamlines. Non-orthogonality of the incident X-ray beam and the rotation axis (if not allowed for) or an off-centre crystal will also give rise to apparent changes in crystal orientation with spindle rotation.

The crystal mosaicity can be estimated by visual inspection and refined by post refinement. Refined values are quite reliable when the mosaic spread is less than about 0.5°, but become more dependent on the rocking-curve model for the high mosaicities that are often associated with frozen crystals. The presence of diffuse scatter, which appears as haloes around the Bragg diffraction spots, presents further difficulties in determining the correct mosaic spread. When processing coarse-sliced images it is preferable to overestimate the mosaic spread slightly (rather than underestimate it). This will result in an increase in random errors (by adding in the X-ray background from an image on which the spot is not actually present), whereas using too small a value can give systematic errors (by underestimating the number of images on which the spot lies).

11.2.2.2. Detector parameters

Detector calibration is essential for high data quality. Both the spatial distortion and the non-uniformity of response of the detector must be accurately known, and it is equally important that these corrections are stable over the timescale of the experiment (and preferably for much longer).

Finally, the crystal-to-detector distance, the detector orientation and the direct-beam position must be refined and continuously updated during integration, using observed spot positions. The crystal-to-detector distance can vary during data collection if the crystal is not exactly centred on the rotation axis, and the direct-beam position can move after a beam refill at a synchrotron. For image-plate detectors with two (or more) plates, the direct-beam position and detector distance often differ slightly for different plates.

With appropriate care, it is normally possible to predict reflection positions on the detector to an accuracy of 20–30 µm, or a fraction of the pixel size, particularly for highly collimated X-ray beams available at synchrotron sources. This level of accuracy is necessary to minimize possible systematic errors, particularly in the case of profile fitting.

11.2.3. Methods of integration

There are two quite distinct procedures available for determining the integrated intensities: summation integration and profile fitting. Summation integration involves simply adding the pixel values for all pixels lying within the area of a spot, and then subtracting the estimated background contribution to the same pixels. Profile fitting (Diamond, 1969; Ford, 1974; Rossmann, 1979) assumes that the actual spot shape or profile is known (in two or three dimensions) and the intensity is derived by finding the scale factor that, when applied to the known (or standard) profile, gives the best fit to the observed spot profile. In practice,

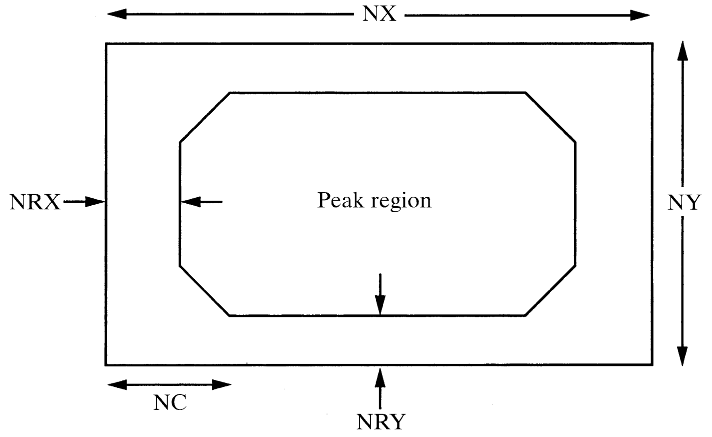

Figure 11.2.4.1
The measurement-box definition used in *MOSFLM*. The measurement box has overall dimensions of NX by NY pixels (both odd integers). The separation between peak and background pixels is defined by the widths of the background rims (NRX and NRY) and the corner cutoff (NC). The size of the peak region is optimized separately for each of the standard profiles.

profile fitting requires two separate steps: the determination of the standard profiles and the evaluation of the profile-fitting intensities. As will be shown later, profile fitting results in a reduction in the random error associated with weak intensities, but offers no improvement for very high intensities.

11.2.4. The measurement box

X-ray scattering from air, the sample holder and the specimen itself gives rise to a general background in the images which has to be subtracted in order to obtain the Bragg intensities. Ideally, the background should be measured for the same pixels used to record the Bragg diffraction spot, but this is not usually practical and the background is determined using pixels immediately adjacent to the spot. In practice, the pixels to be used for the determination of the background (background pixels) and those to be used for evaluating the intensity (peak pixels) are defined using a 'measurement box'. This is a rectangular box of pixels centred on the predicted spot position. Each pixel within the box is classified as being a background or a peak pixel (or neither). This mask can either be defined by the user, or the classification can be made automatically by the program. An example of a possible measurement-box definition is given in Fig. 11.2.4.1. The background parameters NRX, NRY and NC can be optimized automatically by maximizing the ratio of the intensity divided by its standard deviation, in a manner analogous to that described by Lehmann & Larsen (1974). It is generally assumed that the background can be adequately modelled as a plane, and the plane constants are determined using the background pixels. This allows the background to be estimated for the peak pixels, so that the background-corrected intensity can be calculated.

11.2.5. Integration by simple summation

11.2.5.1. Determination of the best background plane

The background plane constants a, b, c are determined by minimizing

$$R_1 = \sum_{i=1}^{n} w_i(\rho_i - ap_i - bq_i - c)^2, \qquad (11.2.5.1)$$

where ρ_i is the total counts at the pixel with coordinates $(p_i q_i)$ with respect to the centre of the measurement box, and the summation is over the n background pixels. w_i is a weight which should ideally be the inverse of the variance of ρ_i. Assuming that the variance is determined by counting statistics, this gives

$$w_i = 1\big/GE(\rho_i), \qquad (11.2.5.2)$$

where G is the gain of detector, which converts pixel counts to equivalent X-ray photons, and $E(\rho_i)$ is the expectation value of the background counts ρ_i. In practice, the variation in background across the measurement box is usually sufficiently small that all weights can be considered to be equal.

This gives the following equations for a, b and c, as given in Rossmann (1979),

$$\begin{pmatrix} \sum p^2 & \sum pq & \sum p \\ \sum pq & \sum q^2 & \sum q \\ \sum p & \sum q & n \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} \sum p\rho \\ \sum q\rho \\ \sum \rho \end{pmatrix}, \qquad (11.2.5.3)$$

where all summations are over the n background pixels.

11.2.5.1.1. Outlier rejection

It is not unusual for the diffraction pattern to display features other than the Bragg diffraction spots from the crystal of interest. Possible causes are the presence of a satellite crystal or twin component, white-radiation streaks, cosmic rays or zingers. In order to minimize their effect on the determination of the background plane constants, the following outlier rejection algorithm is employed:

1. Determine the background plane constants using a fraction (say 80%) of the background pixels, selecting those with the *lowest* pixel values.
2. Evaluate the fit of all background pixels to this plane, rejecting those that deviate by more than three standard deviations.
3. Re-determine the background plane using all accepted pixels.
4. Re-evaluate the fit of all accepted pixels and reject outliers. If any new outliers are found, re-determine the plane constants.

The rationale for using a subset of the pixels with the lowest pixel values in step (1) is that the presence of zingers or cosmic rays, or a strongly diffracting satellite crystal, can distort the initial calculation of the background plane so much that it becomes difficult to identify the true outliers. Such features will normally only affect a small percentage of the background pixels and will invariably give higher than expected pixel counts. Selecting a subset with the lowest pixel values will facilitate identification of the true outliers. The initial bias in the resulting plane constant c due to this procedure will be corrected in step (3). Poisson statistics are used to evaluate the standard deviations used in outlier rejection, and the standard deviation used in step (2) is increased to allow for the choice of background pixels in step (1).

11.2.5.2. Evaluating the integrated intensity and standard deviation

The summation integration intensity I_s is given by

$$I_s = \sum_{i=1}^{m}(\rho_i - ap_i - bq_i - c), \qquad (11.2.5.4)$$

where the summation is over the m pixels in the peak region of the measurement box. If the peak region has *mm* symmetry, this simplifies to

$$I_s = \sum_{i=1}^{m}(\rho_i - c). \qquad (11.2.5.5)$$

To evaluate the standard deviation, this can be written as

$$I_s = \sum_{i=1}^{m} \rho_i - (m/n) \sum_{j=1}^{n} \rho_j, \qquad (11.2.5.6)$$

where the second summation is over the n background pixels.

The variance in I_s is

$$\sigma_{I_s}^2 = \sum_{i=1}^{m} \sigma_i^2 + (m/n)^2 \sum_{j=1}^{n} \sigma_j^2. \qquad (11.2.5.7)$$

From Poisson statistics this becomes

$$\sigma_{I_s}^2 = \sum_{i=1}^{m} G\rho_i + (m/n)^2 \sum_{j=1}^{n} G\rho_j \qquad (11.2.5.8)$$

$$= G\left[I_s + I_{\rm bg} + (m/n)(m/n) \sum_{j=1}^{n} \rho_j \right], \qquad (11.2.5.9)$$

where $I_{\rm bg}$ is the background summed over all peak pixels. We can also write

$$I_{\rm bg} \simeq (m/n) \sum_{j=1}^{n} \rho_j \qquad (11.2.5.10)$$

(this is only strictly true if the background region has *mm* symmetry). Then

$$\sigma_{I_s}^2 = G\left[I_s + I_{\rm bg} + (m/n) I_{\rm bg} \right]. \qquad (11.2.5.11)$$

This expression shows the importance of the background ($I_{\rm bg}$) in determining the standard deviation of the intensity. For weak reflections, the Bragg intensity (I_s) is often much smaller than the background ($I_{\rm bg}$), and the error in the intensity is determined entirely by the background contribution.

11.2.5.3. *The effect of instrument or detector errors*

Standard-deviation estimates calculated using (11.2.5.11) are generally in quite good agreement with observed differences between the intensities of symmetry-related reflections for weak or medium intensities. This is particularly true if other sources of systematic error are minimized by measuring the *same* reflections five or more times, by doing multiple exposures of the same small oscillation range and then processing the data in space group $P1$. However, even in this latter case, the agreement between strong intensities is significantly worse than that predicted using equation (11.2.5.11). This is consistent with the observation that it is very unusual to obtain merging R factors lower than 0.01, even for very strong reflections where Poisson statistics would suggest merging R factors should be in the range 0.002–0.003.

An experiment in which a diffraction spot recorded on photographic film was scanned many times on an optical microdensitometer showed that the r.m.s. variation in individual pixel values between the scans was greatest for those pixels immediately surrounding the centre of the spot, where the gradient of the optical density was greatest. One explanation for this observation is that these optical densities will be most sensitive to small errors in positioning the reading head, due to vibration or mechanical defects. A simple model for the instrumental contribution to the standard deviation of the spot intensity is obtained by introducing an additional term for each pixel in the spot peak:

$$\sigma_{\rm ins} = K \frac{\delta\rho}{\delta x}, \qquad (11.2.5.12)$$

where $\delta\rho/\delta x$ is the average gradient and K is a proportionality constant. Taking a triangular reflection profile, the gradient and integrated intensity are related by

$$I_s = \frac{1}{12}\left(x^3 + 3x^2 + 5x + 3\right) \frac{\delta\rho}{\delta x}, \qquad (11.2.5.13)$$

where x is the half-width of the reflection (in pixels).

Writing

$$A = \frac{1}{12}\left(x^3 + 3x^2 + 5x + 3\right) \qquad (11.2.5.14)$$

gives

$$\sigma_{\rm ins} = (K/A) I_s, \qquad (11.2.5.15)$$

where the factor A allows for differences in spot size and K is, ideally, a constant for a given instrument.

The total variance in the integrated intensity is then

$$\sigma_{\rm tot}^2 = \sigma_{I_s}^2 + m\sigma_{\rm ins}^2 \qquad (11.2.5.16)$$

$$= G\left[I_s + I_{\rm bg} + (m/n) I_{\rm bg} \right] + m(K/A)^2 I_s^2. \qquad (11.2.5.17)$$

A value for K can be determined by comparing the goodness-of-fit of the standard profiles to individual reflection profiles (of fully recorded reflections) with that calculated from combined Poisson statistics and the instrument error term. Standard deviations estimated using (11.2.5.17) give much more realistic estimates than those based on (11.2.5.11), even for data collected with charge-coupled-device (CCD) detectors where the physical model for the source of the error is clearly not appropriate.

11.2.6. Integration by profile fitting

Providing the background and peak regions are correctly defined, summation integration provides a method for evaluating integrated intensities that is both robust and free from systematic error. For weak reflections, however, many of the pixels in the peak region will contain very little signal (Bragg intensity) but will contribute significantly to the noise because of the Poissonian variation in the background [as shown by the $I_{\rm bg}$ term in equation (11.2.5.11)]. Profile fitting provides a means of improving the signal-to-noise ratio for this class of reflection (but will provide no improvement for reflections where the background level is negligible).

11.2.6.1. *Forming the standard profiles*

In order to apply profile-fitting methods, the first requirement is to derive a 'standard' profile that accurately represents the true reflection profile. Although analytical functions can be used, it is difficult to define a simple function that will cope adequately with the wide variation in spot shapes that can arise in practice. Most programs therefore rely on an empirical profile derived by summing many different spots. The optimum profile is that which provides the best fit to all the contributing reflections, *i.e.* that which minimizes

$$R_2 = \sum_h w_j(h)\left[K_h P_j - \rho_j(h)_{\rm corr} \right]^2, \qquad (11.2.6.1)$$

where P_j is the profile value for the jth pixel, $\rho_j(h)_{\rm corr}$ is the observed background-corrected count at that pixel for reflection h, K_h is a scale factor and $w_j(h)$ is a weight for the jth pixel of reflection h. The summation extends over all reflections contributing to the profile. The weight is given by

$$w_j(h) = 1/\sigma_{hj}^2, \qquad (11.2.6.2)$$

and from Poisson statistics σ_{hj}^2 is the expectation value of the counts at pixel j, and is given by

$$\sigma_{hj}^2 = K_h P_j + \left(a_h p_j + b_h q_j + c_h \right). \qquad (11.2.6.3)$$

After Rossmann (1979), the summation integration intensity $I_s(h)$ can be used to derive a value for K_h:

$$I_s(h) = K_h \sum_{j=1}^{m} P_j. \qquad (11.2.6.4)$$

In equations (11.2.6.3) and (11.2.6.4), as the profile values P_j are not yet determined, a preliminary profile derived, for example, from simple summation of strong reflections used in the detector-parameter refinement can be used, which will give acceptable weights for use in equation (11.2.6.1).

This method of deriving the standard profile is only appropriate for fully recorded reflections. However, in many cases there will be very few or no fully recorded reflections on each image. In such cases the profile is determined by simply adding together the background-corrected pixel counts from all contributing reflections. In the program *MOSFLM* (Leslie, 1992), the profiles are determined using reflections on, typically, ten or more successive images, so that partials will be summed to give the correct fully recorded profile for the majority of the contributing reflections. Tests carried out using standard profiles derived using only fully recorded reflections and equation (11.2.6.1), or using both fully recorded and partially recorded reflections and simple summation, give data of the same quality as judged by the merging statistics.

The reflection profile changes across the face of the detector, due to obliquity of incidence, changes in the projected diffracting volume and geometric factors. In the *MOSFLM* program, this variation is accommodated by determining several standard profiles (typically nine or 25) for different regions of the detector. When evaluating the profile-fitted intensity for a given reflection, a weighted sum of the nearest standard profiles is calculated to provide the best estimate of the true profile at that position on the detector. For the central regions of the detector there will be four contributing profiles, while at the edges there will be between one and three. The weights assigned to each profile vary linearly with the distance from the reflection to the centres of the regions used in determining the standard profiles. An alternative procedure used in *DENZO* (Otwinowski & Minor, 1997) is to evaluate a new profile for each reflection based on spots lying within a pre-specified radius.

11.2.6.2. *Evaluation of the profile-fitted intensity*

Given an appropriate standard profile, the reflection intensity for fully recorded reflections is evaluated by determining the scale factor K and background plane constants a, b, c which minimize

$$R_3 = \sum w_i(KP_i + ap_i + bq_i + c - \rho_i)^2, \qquad (11.2.6.5)$$

where the summation is over all valid pixels in the measurement box. As before,

$$w_i = 1/\sigma_i^2 \qquad (11.2.6.6)$$

and

$$\begin{aligned}\sigma_i^2 &= \text{expectation value of the counts at pixel } i\\ &= ap_i + bq_i + c + JP_i. \qquad (11.2.6.7)\end{aligned}$$

In order to calculate the weights, the background plane constants and summation integration intensity I_s are evaluated as described in Section 11.2.5, at the same time identifying any outliers in the background. The summation integration intensity is used to evaluate the scale factor J in equation (11.2.6.7) using

$$I_s = J \sum_i P_i. \qquad (11.2.6.8)$$

In equation (11.2.6.5), the summation is over all valid pixels within the measurement box. This excludes pixels that are overlapped by neighbouring spots (if any) and any outliers identified in the background region.

Minimizing R_3 with respect to K, a, b and c leads to four linear equations from which K, a, b and c can be determined:

$$\begin{pmatrix} \sum wP^2 & \sum wpP & \sum wqP & \sum wP \\ \sum wpP & \sum wp^2 & \sum wpq & \sum wp \\ \sum wqP & \sum wpq & \sum wq^2 & \sum wq \\ \sum wP & \sum wp & \sum wq & \sum w \end{pmatrix} \begin{pmatrix} K \\ a \\ b \\ c \end{pmatrix} = \begin{pmatrix} \sum wP\rho \\ \sum wp\rho \\ \sum wq\rho \\ \sum w\rho \end{pmatrix}. \qquad (11.2.6.9)$$

The profile-fitted intensity I_p is then given by

$$I_p = K \sum_i P_i. \qquad (11.2.6.10)$$

The standard deviation in the profile-fitted intensity is given by

$$\begin{aligned}\sigma_{I_p}^2 &= \sigma_K^2 \Bigl(\sum_i P_i\Bigr)^2 \qquad (11.2.6.11)\\ &= \Bigl(\sum_i^N w_i\Delta_i^2/(N-4)\Bigr) A_{KK}^{-1} \Bigl(\sum_i P_i\Bigr)^2, \qquad (11.2.6.12)\end{aligned}$$

where

$$\Delta_i = (KP_i + ap_i + bq_i + c - \rho_i), \qquad (11.2.6.13)$$

N is the number of pixels in the summation and A_{KK}^{-1} is the diagonal element for the scale factor K of the inverse normal matrix (used to minimize R_3).

In the case of partially recorded reflections, it is no longer valid to fit the sum of the scaled standard profile and a background plane to all pixels in the measurement box. Partially recorded reflections can have a profile that differs significantly from the standard profile, with the result that the background plane constants take on physically unreasonable values in an attempt to compensate for this difference. Therefore, for partially recorded reflections, the summation in equation (11.2.6.5) is restricted to pixels in the peak region of the measurement box. Minimizing R_3 with respect to the scale factor K then gives

$$\begin{aligned}I_p &= K\sum P_i \qquad (11.2.6.14)\\ &= \Bigl(\sum w_iP_i\rho_i - a\sum w_iP_ip_i - b\sum w_iP_iq_i - c\sum w_iP_i\Bigr)\sum P_i \Big/ \sum w_iP_i^2, \qquad (11.2.6.15)\end{aligned}$$

where all summations are over the peak region only.

It is not possible to derive a standard deviation for partially recorded reflections based on the fit of the scaled standard profile (because partially recorded reflections have a different spot profile). For these reflections, the standard deviation can be calculated using equation (11.2.5.17).

11.2.6.3. *Modifications for very close spots*

In order to apply equation (11.2.6.5), it is necessary to exclude all pixels in the measurement box that are overlapped by a neighbouring spot. This applies not only to the pixels of the reflection being integrated, but also to the pixels of all the reflections used to form the standard profile. Consequently, a pixel should be excluded even if it is only overlapped by a neighbouring spot for one of the reflections used in forming the standard profile. When processing data from large unit cells, this can lead to a very high percentage of the background pixels being rejected and therefore a poor determination of the background plane parameters. In these circumstances, the background plane is determined using only background pixels and excluding only those pixels that are overlapped by neighbours for the reflection actually being integrated. The profile-fitted intensity for both fully recorded and partially recorded reflections is then evaluated in the way described for partially recorded reflections in Section 11.2.6.2, with the summation in equation (11.2.6.15) extending only over peak pixels. The standard deviation in the intensity for partially recorded reflections is derived from equation (11.2.5.17) as before. For fully recorded reflections, the standard deviation has two components: the first is based on the fit of the scaled standard profile to the reflection profile and the second on the contribution from the background:

$$\sigma_I^2 = \sigma_{\rm prof}^2 + \sigma_{\rm bg}^2 \qquad (11.2.6.16)$$

$$= \left[\sum_{i=1}^{m} w_i\Delta_i^2\Big/(m-1)\right]\left[\left(\sum_{i=1}^{m}P_i\right)^2\Big/\sum_{i=1}^{m}w_iP_i^2\right] + (m/n)\sum_{i=1}^{n}(\rho_i - ap_i - bq_i - c)^2, \qquad (11.2.6.17)$$

where m and n are the number of pixels in the peak and background, respectively.

11.2.6.4. *Profile fitting very strong reflections*

For very strong reflections, the background level is very small and equation (11.2.6.15) reduces to

$$I_p \simeq \textstyle\sum w_iP_i\rho_i \sum P_i\Big/\sum w_iP_i^2, \qquad (11.2.6.18)$$

and the weights are given by

$$w_i \simeq 1\big/JP_i. \qquad (11.2.6.19)$$

Substituting for w_i in (11.2.6.18) gives

$$I_p \simeq \textstyle\sum \rho_i. \qquad (11.2.6.20)$$

As pointed out by Z. Otwinowski (personal communication), this shows that for correctly weighted profile fitting, the profile-fitted intensity reduces to the summation integration intensity for very strong intensities.

11.2.6.5. *Profile fitting very weak reflections*

For very weak reflections, all pixels will have very similar counts and therefore all the weights will be the same. For simplicity, consider the case where the profile fit is evaluated only for the peak pixels, then equation (11.2.6.15) reduces to

$$I_P \simeq \textstyle\sum P_i(\rho_i - ap_i - bq_i - c)\sum P_i\Big/\sum P_i^2. \qquad (11.2.6.21)$$

The second and third summations in this equation depend only on the shape of the standard profile. This shows that the intensity is a weighted sum of the individual background-corrected pixel counts (rather than a simple unweighted sum, as is the case for summation integration). Because the values of P_i are a maximum in the centre of the spot, this will place a higher weight on those pixels where the contribution of the Bragg diffraction is greatest, and a very low weight on the peripheral pixels where the Bragg diffraction is weakest. In this way, profile fitting improves the signal-to-noise ratio without the risk of introducing any systematic error that may result by simply reducing the size of the peak region for weak spots.

11.2.6.6. *Improvement provided by profile fitting weak reflections*

For very weak reflections, where all the weights w_i are approximately the same, the variance in I_p using equation (11.2.6.21) is given by

$$\sigma_{I_p}^2 = \textstyle\sum {\rm Var}(\rho_i - ap_i - bq_i - c)P_i^2\left(\sum P_i\Big/\sum P_i^2\right)^2. \qquad (11.2.6.22)$$

Assuming a flat background and very weak intensity, then from Poisson statistics

$${\rm Var}(\rho_i - ap_i - bq_i - c) \simeq G\rho_i, \qquad (11.2.6.23)$$

and as ρ_i has approximately the same value (ρ) for all pixels,

$$\sigma_{I_p}^2 = G\rho\textstyle\sum P_i^2\left(\sum P_i\Big/\sum P_i^2\right)^2 \qquad (11.2.6.24)$$

$$= G\rho\left(\textstyle\sum P_i\right)^2\Big/\textstyle\sum P_i^2. \qquad (11.2.6.25)$$

The variance in the summation integration intensity is simply

$$\sigma_{I_s}^2 = Gm\rho. \qquad (11.2.6.26)$$

The ratio of the variances is thus

$$\sigma_{I_s}^2\big/\sigma_{I_p}^2 = m\textstyle\sum P_i^2\Big/\left(\sum P_i\right)^2. \qquad (11.2.6.27)$$

For a typical spot profile, the right-hand side (which depends only on the shape of the standard profile) has a value of 2, showing that profile fitting can reduce the standard deviation in the integrated intensity by a factor of $(2)^{1/2}$.

11.2.6.7. *Other benefits of profile fitting*

11.2.6.7.1. *Incompletely resolved spots*

If adjacent spots are not fully resolved, there will be a systematic error in the integrated intensity which will be largest for weak spots that are adjacent to very strong spots. However, the profile-fitted intensity will be affected less than the summation integration intensity, because the peripheral pixels (where the influence of neighbouring spots is greatest) are downweighted relative to the central pixels (where the neighbours will have least influence).

Further steps can be taken to minimize the errors caused by overlapping spots. Firstly, when forming the standard profiles, reflections are only included if they are significantly stronger than their nearest neighbours. This will minimize the errors in the standard profiles. Secondly, when evaluating the profile-fitted intensity of a particular reflection, pixels can be omitted if they are adjacent to a pixel that is part of a neighbouring spot (rather than having to be part of that spot).

11.2.6.7.2. *Elimination of peak pixel outliers*

In the same way that outliers in the background region can be identified and rejected (see Section 11.2.5.1.1), it is possible in principle to identify outliers in the peak region of fully recorded reflections as those pixels whose deviation from the scaled standard profile is significantly greater than that expected from counting statistics. This approach works well if the feature that gives rise to the outliers affects only a small fraction of the peak pixels and gives rise to large deviations, and this is the case for some zingers or dead pixels, and for diffraction from small ice crystals when collecting data from cryo-cooled samples.

Another source of outliers is the encroachment of a strong neighbouring spot into the peak region, as discussed in Section 11.2.6.7.1. When dealing with peripheral pixels, the outlier test can be applied to both fully recorded and partially recorded reflections, but a high σ cutoff (*e.g.* 10–20) must be used to avoid rejecting pixels that do not fit the profile simply because they correspond to a partially recorded spot.

11.2.6.7.3. Estimation of overloaded reflections

Owing to the limited dynamic range of current detectors, it is common for many low-resolution spots to contain saturated pixels. Providing the saturation level of the detector is known, such pixels can simply be excluded from the profile fitting, allowing a reasonable estimate of the true intensity (except when the majority of the pixels are saturated). A knowledge of the strong intensities is essential for structure solution based on molecular replacement techniques, and so this is a very useful additional feature of profile fitting.

11.2.6.8. Profile fitting partially recorded reflections

Greenhough & Suddath (1986) have shown that when profile fitting is applied to partially recorded reflections this leads to a systematic error in the individual intensities, but there is no systematic error in the total summed intensity. Although their analysis is strictly only applicable to the case of unweighted profile fitting, experience has shown that even when using weighted profile fitting there is no evidence of systematic errors in the summed profile-fitted intensities of partially recorded reflections. This is particularly important as many data sets collected from frozen crystals have few, if any, fully recorded reflections.

11.2.6.9. Systematic errors in profile-fitted intensities

The fundamental assumption in profile fitting is that the standard profiles accurately reflect the true profile of the reflection being integrated. Errors in the standard profile will result in systematic errors in the profile-fitted intensities. While these errors will often be small compared to the random (Poissonian) error for weak reflections, this is not necessarily the case for strong reflections, as the systematic error is typically a small percentage of the total intensity. Because the standard profiles are derived from the summation of many contributing reflections, small positional errors in spot prediction will lead to a broadening of the standard profile relative to the profile of an individual spot. The same broadening can occur because of the finite sampling interval in the image, which means that a predicted spot position can lie up to half a pixel away from the centre of the measurement box. This error can be minimized by interpolating the pixel values in the image onto a grid which is centred exactly on the predicted position, but the interpolation step itself will inevitably distort the reflection profile. In spite of these difficulties, providing adequate care is taken to determine the crystal and detector parameters accurately (as mentioned in Section 11.2.2), so that the spot positions are predicted to within a small fraction of the overall spot width, there is no suggestion (from merging statistics at least) for significant systematic error, even in the stronger intensities.

I would like to thank Dr A. J. Wonacott, Dr P. Brick and Dr P. R. Evans for many stimulating and critical discussions on all aspects of data integration.

Chapter 11.3. Integration, scaling, space-group assignment and post refinement

W. Kabsch

11.3.1. Introduction

The key steps in the processing of diffraction data from single crystals involve (i) modelling of the observed reflection positions in the detector plane, (ii) integration of diffraction intensities, (iii) data correction, scaling and post refinement and (iv) space-group assignment. Much of the theory and many of the methods for carrying out these steps were developed about three decades ago for processing rotation data recorded on film and were subsequently extended in order to fully exploit the capabilities of a variety of electronic area detectors; some CCD (charge-coupled device) and multiwire detectors as well as a new pixel detector specially developed for data collection at synchrotron beamlines allow the recording of finely sliced rotation data because of their fast data read-out. In this article, the principles of the methods are described as employed by the program *XDS* (Chapter 11.6). These apply equally well to rotation images covering small or large oscillation ranges. A large number of other data-processing systems have been developed which differ in the details of the implementations. Some of these packages are described elsewhere in this volume (see Chapters 11.1, 11.2 and 11.4). The theory and practice of processing fine-sliced data have been discussed by Pflugrath (1997).

11.3.2. Modelling rotation images

The observed diffraction pattern, *i.e.* the positions of the reflections recorded on the rotation-data images, is controlled by a small set of parameters which must be accurately determined before integration can start. Approximate values for some of these parameters are given by the experimental setup, whereas others may be completely unknown and must be obtained from the rotation images. This is achieved by the automatic location of strong diffraction spots, the extraction of a primitive lattice basis that yields integer indices for the observed reflections and the subsequent refinement of all parameters to minimize the discrepancies between observed and calculated spot positions in the data images.

11.3.2.1. Coordinate systems and parameters

In the rotation method, the incident-beam wavevector $\mathbf{S}_0$ of length $1/\lambda$ (where λ is the wavelength) is fixed while the crystal is rotated around a fixed axis described by a unit vector $\mathbf{m}_2$. $\mathbf{S}_0$ points from the X-ray source towards the crystal. It is assumed that the incident beam and the rotation axis intersect at one point at which the crystal must be located. This point is defined as the origin of a right-handed orthonormal laboratory coordinate system $\{\mathbf{l}_1, \mathbf{l}_2, \mathbf{l}_3\}$. This fixed but otherwise arbitrary system is used as a reference frame to specify the setup of the diffraction experiment.

Diffraction data are assumed to be recorded on a fixed planar detector. A right-handed orthonormal detector coordinate system $\{\mathbf{d}_1, \mathbf{d}_2, \mathbf{d}_3\}$ is defined such that a point with coordinates X, Y in the detector plane is represented by the vector $(X - X_0)\mathbf{d}_1 + (Y - Y_0)\mathbf{d}_2 + F\mathbf{d}_3$ with respect to the laboratory coordinate system. The origin X_0, Y_0 of the detector plane is found at a distance $|F|$ from the crystal position. It is assumed that the diffraction data are recorded on adjacent non-overlapping rotation images, each covering a constant oscillation range Δ_φ, with image No. 1 starting at spindle angle φ_0.

Diffraction geometry is conveniently expressed with respect to a right-handed orthonormal goniostat system $\{\mathbf{m}_1, \mathbf{m}_2, \mathbf{m}_3\}$. It is constructed from the rotation axis and the incident-beam direction such that $\mathbf{m}_1 = (\mathbf{m}_2 \times \mathbf{S}_0)/|\mathbf{m}_2 \times \mathbf{S}_0|$ and $\mathbf{m}_3 = \mathbf{m}_1 \times \mathbf{m}_2$. The origin of the goniostat system is defined to coincide with the origin of the laboratory system.

Finally, a right-handed crystal coordinate system $\{\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3\}$ and its reciprocal basis $\{\mathbf{b}_1^*, \mathbf{b}_2^*, \mathbf{b}_3^*\}$ are defined to represent the unrotated crystal, *i.e.* at rotation angle $\varphi = 0°$, such that any reciprocal-lattice vector can be expressed as $\mathbf{p}_0^* = h\mathbf{b}_1^* + k\mathbf{b}_2^* + l\mathbf{b}_3^*$, where h, k, l are integers.

As shown in Section 11.3.2.2, the location of all diffraction peaks recorded in the data images can be computed from the parameters $\mathbf{S}_0$, $\mathbf{m}_2$, $\mathbf{b}_1$, $\mathbf{b}_2$, $\mathbf{b}_3$, X_0, Y_0, F, $\mathbf{d}_1$, $\mathbf{d}_2$, $\mathbf{d}_3$, φ_0 and Δ_φ. In addition, knowledge of the shape and extent of the diffraction spots is required for accurate estimations of their intensities. This can be achieved by a Gaussian model involving two parameters: the standard deviations of the reflecting range, σ_M, and of the beam divergence, σ_D (see Section 11.3.2.3). This leads to an integration region around the spot defined by the parameters δ_M and δ_D, which are typically chosen to be 6–10 times larger than σ_M and σ_D, respectively.

11.3.2.2. Spot prediction

Let $\mathbf{p}_0^*$ denote any arbitrary reciprocal-lattice vector if the crystal has not been rotated, *i.e.* at rotation angle $\varphi = 0°$. Depending on the diffraction geometry, $\mathbf{p}_0^*$ may be rotated into a position fulfilling the reflecting condition. The required rotation angle φ and the coordinates X, Y of the diffracted beam at its intersection with the detector plane can be found from $\mathbf{p}_0^*$ as follows.

$\mathbf{p}_0^*$ can be expressed by its components with respect to the orthonormal goniostat system as

$$\mathbf{p}_0^* = \mathbf{m}_1(\mathbf{m}_1 \cdot \mathbf{p}_0^*) + \mathbf{m}_2(\mathbf{m}_2 \cdot \mathbf{p}_0^*) + \mathbf{m}_3(\mathbf{m}_3 \cdot \mathbf{p}_0^*).$$

Rotation by φ around axis $\mathbf{m}_2$ changes $\mathbf{p}_0^*$ into $\mathbf{p}^*$,

$$\begin{aligned}\mathbf{p}^* &= D(\mathbf{m}_2, \varphi)\mathbf{p}_0^* \\ &= \mathbf{m}_2(\mathbf{m}_2 \cdot \mathbf{p}_0^*) + [\mathbf{p}_0^* - \mathbf{m}_2(\mathbf{m}_2 \cdot \mathbf{p}_0^*)]\cos\varphi + \mathbf{m}_2 \times \mathbf{p}_0^* \sin\varphi \\ &= \mathbf{m}_1(\mathbf{m}_1 \cdot \mathbf{p}_0^* \cos\varphi + \mathbf{m}_3 \cdot \mathbf{p}_0^* \sin\varphi) + \mathbf{m}_2\mathbf{m}_2 \cdot \mathbf{p}_0^* \\ &\quad + \mathbf{m}_3(\mathbf{m}_3 \cdot \mathbf{p}_0^* \cos\varphi - \mathbf{m}_1 \cdot \mathbf{p}_0^* \sin\varphi) \\ &= \mathbf{m}_1(\mathbf{m}_1 \cdot \mathbf{p}^*) + \mathbf{m}_2(\mathbf{m}_2 \cdot \mathbf{p}^*) + \mathbf{m}_3(\mathbf{m}_3 \cdot \mathbf{p}^*).\end{aligned}$$

The incident-beam and diffracted-beam wavevectors, $\mathbf{S}_0$ and $\mathbf{S}$, have their termini on the Ewald sphere and satisfy the Laue equations

$$\mathbf{S} = \mathbf{S}_0 + \mathbf{p}^*, \quad \mathbf{S}^2 = \mathbf{S}_0^2 \quad \Longrightarrow \quad \mathbf{p}^{*2} = -2\mathbf{S}_0 \cdot \mathbf{p}^* = \mathbf{p}_0^{*2}.$$

If $\rho = [\mathbf{p}_0^{*2} - (\mathbf{p}_0^* \cdot \mathbf{m}_2)^2]^{1/2}$ denotes the distance of $\mathbf{p}_0^*$ from the rotation axis, solutions for $\mathbf{p}^*$ and φ can be obtained in terms of $\mathbf{p}_0^*$ as

Copyright © 2012 International Union of Crystallography

$$\begin{aligned}
&\mathbf{p}^* \cdot \mathbf{m}_3 = [-\mathbf{p}_0^{*2}/2 - (\mathbf{p}_0^* \cdot \mathbf{m}_2)(\mathbf{S}_0 \cdot \mathbf{m}_2)]/\mathbf{S}_0 \cdot \mathbf{m}_3\\
&\mathbf{p}^* \cdot \mathbf{m}_2 = \mathbf{p}_0^* \cdot \mathbf{m}_2\\
&\mathbf{p}^* \cdot \mathbf{m}_1 = \pm[\rho^2 - (\mathbf{p}^* \cdot \mathbf{m}_3)^2]^{1/2}\\
&\quad \cos\varphi = [(\mathbf{p}^* \cdot \mathbf{m}_1)(\mathbf{p}_0^* \cdot \mathbf{m}_1) + (\mathbf{p}^* \cdot \mathbf{m}_3)(\mathbf{p}_0^* \cdot \mathbf{m}_3)]/\rho^2\\
&\quad \sin\varphi = [(\mathbf{p}^* \cdot \mathbf{m}_1)(\mathbf{p}_0^* \cdot \mathbf{m}_3) - (\mathbf{p}^* \cdot \mathbf{m}_3)(\mathbf{p}_0^* \cdot \mathbf{m}_1)]/\rho^2.
\end{aligned}$$

In general there are two solutions according to the sign of $\mathbf{p}^* \cdot \mathbf{m}_1$. If $\rho^2 < (\mathbf{p}^* \cdot \mathbf{m}_3)^2$ or $\mathbf{p}_0^{*2} > 4\mathbf{S}_0^2$ the Laue equations have no solution and the reciprocal-lattice point $\mathbf{p}_0^*$ is in the 'blind' region.

If $F\mathbf{S} \cdot \mathbf{d}_3 > 0$ the diffracted beam intersects the detector plane at the point

$$\begin{aligned}
F\mathbf{S}/\mathbf{S} \cdot \mathbf{d}_3 &= (F\mathbf{S} \cdot \mathbf{d}_1/\mathbf{S} \cdot \mathbf{d}_3)\mathbf{d}_1 + (F\mathbf{S} \cdot \mathbf{d}_2/\mathbf{S} \cdot \mathbf{d}_3)\mathbf{d}_2 + F\mathbf{d}_3\\
&= (X - X_0)\mathbf{d}_1 + (Y - Y_0)\mathbf{d}_2 + F\mathbf{d}_3,
\end{aligned}$$

which leads to a diffraction spot recorded at detector coordinates

$$\begin{aligned}
X &= X_0 + F\mathbf{S} \cdot \mathbf{d}_1/\mathbf{S} \cdot \mathbf{d}_3,\\
Y &= Y_0 + F\mathbf{S} \cdot \mathbf{d}_2/\mathbf{S} \cdot \mathbf{d}_3.
\end{aligned}$$

11.3.2.3. Standard spot shape

A reciprocal-lattice point crosses the Ewald sphere by the shortest route only if the crystal happens to be rotated about an axis perpendicular to both the diffracted-beam and incident-beam wavevectors, the 'β axis' $\mathbf{e}_1 = \mathbf{S} \times \mathbf{S}_0/|\mathbf{S} \times \mathbf{S}_0|$, as introduced by Schutt & Winkler (1977). Rotation around the fixed axis $\mathbf{m}_2$, as enforced by the rotation camera, thus leads to an increase in the length of the shortest path by the factor $1/|\mathbf{e}_1 \cdot \mathbf{m}_2|$. This motivated the introduction of a coordinate system $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$, specific for each reflection, which has its origin on the surface of the Ewald sphere at the terminus of the diffracted beam wavevector $\mathbf{S}$,

$$\begin{aligned}
\mathbf{e}_1 &= \mathbf{S} \times \mathbf{S}_0/|\mathbf{S} \times \mathbf{S}_0|,\\
\mathbf{e}_2 &= \mathbf{S} \times \mathbf{e}_1/|\mathbf{S} \times \mathbf{e}_1|,\\
\mathbf{e}_3 &= (\mathbf{S} + \mathbf{S}_0)/|\mathbf{S} + \mathbf{S}_0|.
\end{aligned}$$

The unit vectors $\mathbf{e}_1$ and $\mathbf{e}_2$ are tangential to the Ewald sphere, while $\mathbf{e}_3$ is perpendicular to $\mathbf{e}_1$ and $\mathbf{p}^* = \mathbf{S} - \mathbf{S}_0$. The shape of a reflection, as represented with respect to $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$, then no longer contains geometrical distortions resulting from the fixed rotation axis of the camera and the oblique incidence of the diffracted beam on a flat detector. Instead, all reflections appear as if they had followed the shortest path through the Ewald sphere and had been recorded on the surface of the sphere.

A detector pixel at X', Y' in the neighbourhood of the reflection centre X, Y, when the crystal is rotated by φ' instead of φ, is mapped to the profile coordinates ε_1, ε_2, ε_3 by the following procedure:

$$\begin{aligned}
&\mathbf{S}' = \frac{(X' - X_0)\mathbf{d}_1 + (Y' - Y_0)\mathbf{d}_2 + F\mathbf{d}_3}{\lambda \cdot [(X' - X_0)^2 + (Y' - Y_0)^2 + F^2)]^{1/2}}\\
&\varepsilon_1 = \mathbf{e}_1 \cdot (\mathbf{S}' - \mathbf{S})180/(|\mathbf{S}|\pi)\\
&\varepsilon_2 = \mathbf{e}_2 \cdot (\mathbf{S}' - \mathbf{S})180/(|\mathbf{S}|\pi)\\
&\varepsilon_3 = \mathbf{e}_3 \cdot [D(\mathbf{m}_2, \varphi' - \varphi)\mathbf{p}^* - \mathbf{p}^*]180/(|\mathbf{p}^*|\pi) \simeq \zeta \cdot (\varphi' - \varphi)\\
&\quad \zeta = \mathbf{m}_2 \cdot \mathbf{e}_1.
\end{aligned}$$

ζ corrects for the increased path length of the reflection through the Ewald sphere and is closely related to the reciprocal Lorentz correction factor

$$L^{-1} = \frac{|\mathbf{m}_2 \cdot (\mathbf{S} \times \mathbf{S}_0)|}{(|\mathbf{S}| \cdot |\mathbf{S}_0|)} = \left|\zeta \cdot \sin\angle(\mathbf{S}, \mathbf{S}_0)\right|.$$

Because of crystal mosaicity and beam divergence, the intensity of a reflection is smeared around the diffraction maximum. The fraction of total reflection intensity found in the volume element $\mathrm{d}\varepsilon_1\mathrm{d}\varepsilon_2\mathrm{d}\varepsilon_3$ at ε_1, ε_2, ε_3 can be approximated by Gaussian functions:

$$\begin{aligned}
&\omega(\varepsilon_1, \varepsilon_2, \varepsilon_3)\mathrm{d}\varepsilon_1\mathrm{d}\varepsilon_2\mathrm{d}\varepsilon_3\\
&\quad = \frac{\exp(-\varepsilon_1^2/2\sigma_D^2)}{(2\pi)^{1/2}\sigma_D}\,\mathrm{d}\varepsilon_1 \times \frac{\exp(-\varepsilon_2^2/2\sigma_D^2)}{(2\pi)^{1/2}\sigma_D}\,\mathrm{d}\varepsilon_2 \times \frac{\exp(-\varepsilon_3^2/2\sigma_M^2)}{(2\pi)^{1/2}\sigma_M}\,\mathrm{d}\varepsilon_3.
\end{aligned}$$

11.3.2.4. Spot centroids and partiality

The intensity of a reflection can be completely recorded on one image or distributed among several adjacent images. The fraction R_j of total intensity recorded on image j, the 'partiality' of the reflection, can be derived from the distribution function $\omega(\varepsilon_1, \varepsilon_2, \varepsilon_3)$ as

$$\begin{aligned}
R_j &= \int\limits_{-\infty}^{\infty} \mathrm{d}\varepsilon_1 \int\limits_{-\infty}^{\infty} \mathrm{d}\varepsilon_2 \int\limits_{\zeta[\varphi_0+(j-1)\Delta_\varphi-\varphi]}^{\zeta(\varphi_0+j\Delta_\varphi-\varphi)} \mathrm{d}\varepsilon_3\, \omega(\varepsilon_1, \varepsilon_2, \varepsilon_3)\\
&= \frac{1}{(2\pi)^{1/2}\sigma_M/|\zeta|} \int\limits_{\varphi_0+(j-1)\Delta_\varphi}^{\varphi_0+j\Delta_\varphi} \exp[-(\varphi' - \varphi)^2/2(\sigma_M/|\zeta|)^2]\,\mathrm{d}\varphi'\\
&= \big(\mathrm{erf}[|\zeta|(\varphi_0 + j\Delta_\varphi - \varphi)/(2)^{1/2}\sigma_M]\\
&\quad - \mathrm{erf}\{|\zeta|[\varphi_0 + (j-1)\Delta_\varphi - \varphi]/(2)^{1/2}\sigma_M\}\big)/2.
\end{aligned}$$

The integral is evaluated by using a numerical approximation of the error function, erf (Abramowitz & Stegun, 1972).

While the spot centroids in the detector plane are usually good estimates for the detector position of the diffraction maximum, the angular centroid about the rotation axis,

$$Z = \varphi_0 + \Delta_\varphi \cdot \sum_{j=-\infty}^{\infty} (j - \tfrac{1}{2})R_j \simeq \varphi,$$

can be a rather poor guess for the true φ angle of the maximum. Its accuracy depends strongly on the value of φ and the size of the oscillation range $\Delta\varphi$ relative to the mosaicity σ_M of the crystal. For a reflection fully recorded on image j, the value $Z = \varphi_0 + (j - \frac{1}{2}) \cdot \Delta_\varphi$ will always be obtained, which is correct only if φ accidentally happens to be close to the centre of the rotation range of the image. In contrast, the φ angle of a partial reflection recorded on images j and $j + 1$ is closely approximated by $Z = \varphi_0 + [j + (R_{j+1} - R_j)/2] \cdot \Delta_\varphi$. If many images contribute to the spot intensity, $Z(\varphi)$ is always an excellent approximation to the ideal angular position φ when the Laue equations are satisfied; in fact, in the limiting case of infinitely fine-sliced data it can be shown that $\lim_{\Delta\varphi\to 0} Z(\varphi) = \varphi$.

Most refinement routines minimize the discrepancies between the predicted φ angles and their approximations obtained from the observed Z centroids and must therefore carefully distinguish between fully and partially recorded reflections. However, this distinction is unnecessary if the observed Z centroids are instead compared with their analytic forms, because the sensitivity of the centroid positions to the diffraction parameters is correctly weighted in either case (see Section 11.3.2.8).

11.3.2.5. Localizing diffraction spots

Often, some of the parameters controlling the diffraction experiment are either completely unknown or available only at a crude approximation. Accurate values for all parameters must be obtained from the recorded data, *i.e.* from a list of the coordinates of strong spots occurring in the images. As implemented in *XDS*, this list is obtained from all or a subset of the data images by the following procedure. Firstly, each pixel value is compared with the mean value and standard deviation of surrounding pixels in the same image and classified as a strong pixel if its value exceeds the mean by a given multiple (typically 3–5) of the standard deviation. Values of the strong pixels and their location addresses and image running numbers are saved in a file. After the scan, a hash table of sufficient size is allocated to accommodate the strong pixels from the file together with their addresses (for a discussion of the hash technique, see Wirth, 1976). As several strong pixels may belong to the same spot, they are labelled with a unique spot number so that any two such pixels which can be connected by direct strong neighbours in two or three dimensions (if there are adjacent images) belong to the same spot (equivalence class). The labelling is achieved by the highly efficient algorithm for the recording of equivalence classes developed by Rem (see Dijkstra, 1976). On termination, a list X_i', Y_i', Z_i' ($i = 1, \ldots, n$) of the centroids of n strong spots is available.

11.3.2.6. Basis extraction

Any reciprocal-lattice vector can be written in the form $\mathbf{p}_0^* = h\mathbf{b}_1^* + k\mathbf{b}_2^* + l\mathbf{b}_3^*$, where h, k, l are integers and $\mathbf{b}_1^*, \mathbf{b}_2^*, \mathbf{b}_3^*$ are reciprocal basis vectors of the lattice. The basis vectors which describe the orientation, metric and symmetry of the crystal, as well as the reflection indices h, k, l, have to be determined from the list of strong diffraction spots X_i', Y_i', Z_i' ($i = 1, \ldots, n$). Ideally, each spot corresponds to a reciprocal-lattice vector $\mathbf{p}_0^*$ which satisfies the Laue equations after a crystal rotation by φ. Substituting the observed value Z' for the unknown φ angle (see Section 11.3.2.4), $\mathbf{p}_0^*$ is found from the observed spot coordinates as

$$\begin{aligned}\mathbf{p}_0^* &= D(\mathbf{m}_2, -Z')(\mathbf{S}' - \mathbf{S}_0)\\ \mathbf{S}' &= \frac{(X' - X_0)\mathbf{d}_1 + (Y' - Y_0)\mathbf{d}_2 + F\mathbf{d}_3}{\lambda \cdot [(X' - X_0)^2 + (Y' - Y_0)^2 + F^2]^{1/2}}.\end{aligned}$$

Unfortunately, the reciprocal-lattice vectors $\mathbf{p}_{0i}^*$ ($i = 1, \ldots, n$) derived from the above list of strong diffraction spots often contain a number of 'aliens' (spots arising from fluctuations in the background, from ice or from satellite crystals) and a robust method has to be used which is still capable of recognizing the dominant lattice. One approach, suggested by Bricogne (1986) and implemented in a number of variants (Otwinowski & Minor, 1997; Steller *et al.*, 1997), is to identify a lattice basis as the three shortest linear independent vectors $\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3$, each at a maximum of the Fourier transform $\sum_{i=1}^{n} \cos(2\pi \mathbf{b} \cdot \mathbf{p}_{0i}^*)$. Alternatively, a reciprocal basis for the dominant lattice can be determined from short differences between the reciprocal-lattice vectors (Howard, 1986; Kabsch, 1988*a*). As implemented in *XDS*, a lattice basis is found by the following procedure.

The list of given reciprocal-lattice points $\mathbf{p}_{0i}^*$ ($i = 1, \ldots, n$) is first reduced to a small number m of low-resolution difference-vector clusters $\mathbf{v}_\mu^*$ ($\mu = 1, \ldots, m$). f_μ is the population of a difference-vector cluster $\mathbf{v}_\mu^*$; that is, the number of times the difference between any two reciprocal-lattice vectors $\mathbf{p}_{0i}^* - \mathbf{p}_{0j}^*$ is approximately equal to $\mathbf{v}_\mu^*$. In a second step, three linear independent vectors $\mathbf{b}_1^*, \mathbf{b}_2^*, \mathbf{b}_3^*$ are selected among all possible triplets of difference-vector clusters that maximize the function Q,

$$\begin{aligned}Q(\mathbf{b}_1^*, \mathbf{b}_2^*, \mathbf{b}_3^*) &= \sum_{\mu=1}^{m} f_\mu q(\xi_1^\mu, \xi_2^\mu, \xi_3^\mu),\\ q(\xi_1^\mu, \xi_2^\mu, \xi_3^\mu) &= \exp\big(-2\sum_{k=1}^{3}\{[\max(|\xi_k^\mu - h_k^\mu| - \varepsilon, 0)/\varepsilon]^2\\ &\qquad + [\max(|h_k^\mu| - \delta, 0)]^2\}\big),\end{aligned}$$

where

$$\xi_k^\mu = \mathbf{v}_\mu^* \cdot \mathbf{b}_k, \quad \mathbf{v}_\mu^* = \sum_{k=1}^{3} \xi_k^\mu \mathbf{b}_k^*, \quad \mathbf{b}_k \cdot \mathbf{b}_l^* = \begin{cases} 1 & \text{if } k = l\\ 0 & \text{otherwise}\end{cases}$$

and h_k^μ is the nearest integer to ξ_k^μ. The absolute maximum of Q is assumed if all difference vectors can be expressed as small integral multiples of the best triplet. Deviations from this ideal situation are quantified by the quality measure q. The value of q declines sharply if the expansion coefficients ξ_k^μ deviate by more than ε from their nearest integers h_k^μ or if the indices are absolutely larger than δ. The constraint on the allowed range of indices prevents the selection of a spurious triplet of very short difference-vector clusters which might be present in the set. Excellent results have been obtained using $\varepsilon = 0.05$ and $\delta = 5$. The best vector triplet thus found is refined against the observed difference-vector clusters. Finally, a reduced cell is derived from the refined reciprocal-base vector triplet (see Section 11.3.6).

11.3.2.7. Indexing

Once a basis $\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3$ of the lattice is available, integral indices h_i, k_i, l_i must be assigned to each reciprocal-lattice vector $\mathbf{p}_{0i}^*$ ($i = 1, \ldots, n$). Using the integers nearest to $\mathbf{p}_{0i}^* \cdot \mathbf{b}_k$ ($k = 1, 2, 3$) as indices of the reciprocal-lattice vectors $\mathbf{p}_{0i}^*$ could easily lead to a misindexing of longer vectors because of inaccuracies in the basis vectors $\mathbf{b}_k$ and the initial values of the parameters describing the instrumental setup. A more robust solution of the indexing problem is provided by the local indexing method, which assigns only small index differences $h_i - h_j, k_i - k_j, l_i - l_j$ between pairs of neighbouring reciprocal-lattice vectors (Kabsch, 1993).

The reciprocal-lattice points can be considered as nodes of a tree. The tree connects the n points to each other with the connections as its branches. The length ℓ_{ij} of a possible branch between nodes i and j is defined here as

$$\begin{aligned}\ell_{ij} = 1 - \exp\big(-2\sum_{k=1}^{3}\{&[\max(|\xi_k^{ij} - h_k^{ij}| - \varepsilon, 0)/\varepsilon]^2\\ &+ [\max(|h_k^{ij}| - \delta, 0)]^2\}\big),\end{aligned}$$

where

$$\xi_k^{ij} = (\mathbf{p}_{0i}^* - \mathbf{p}_{0j}^*) \cdot \mathbf{b}_k,$$

h_k^{ij} is the nearest integer of ξ_k^{ij} and $k = 1, 2, 3$. Reliable index differences are indicated by short branches; in fact, ℓ_{ij} is 0 if none of the indices h_k^{ij} is absolutely larger than δ and the ξ_k^{ij} are integer values to within ε. Typical values are $\varepsilon = 0.05$ and $\delta = 5$. Defining the length of a tree as the sum of the lengths of its branches, a shortest tree among all n^{n-2} possible trees is determined using the elegant algorithm described by Dijkstra (1976). Starting with arbitrary indices 0, 0, 0 for the root node, the local indexing method then consists of traversing the shortest tree and thereby assigning each node the indices of its predecessor plus the small index differences between the two nodes.

During traversal of the tree, each node is also given a subtree number. Starting with subtree number 1 for the root node, each successor node is given the same subtree number as its predecessor if the length of the connecting branch is below a minimal length $\ell_{\min}$. Otherwise, its subtree number is incremented by 1. Thus, all nodes in the same subtree have internally consistent reflection indices. Defining the size of a subtree by the number of its nodes, 'aliens' are usually found in small subtrees. Finally, a constant index offset is determined such that the centroids of the observed reciprocal-lattice points $\mathbf{p}_{0i}^*$ belonging to the largest subtree and their corresponding grid vectors $\sum_{k=1}^{3} h_k^i \mathbf{b}_k^*$ are as close as possible. This offset is added to the indices of each reciprocal-lattice point.

11.3.2.8. Refinement

For a fixed detector, the diffraction pattern depends on the parameters $\mathbf{S}_0$, $\mathbf{m}_2$, $\mathbf{b}_1$, $\mathbf{b}_2$, $\mathbf{b}_3$, X_0, Y_0, F. Starting values for the parameters can be obtained by the procedures described above, which do not rely on prior knowledge of the crystal orientation, space-group symmetry or unit-cell metric. Better estimates of the parameter values, as required for the subsequent integration step, can be obtained by the method of least squares from the list of n observed indexed reflection centroids h_i, k_i, l_i, X_i', Y_i', Z_i' ($i = 1, \ldots, n$). In this method, the parameters are chosen to minimize a weighted sum of squares of the residuals

$$E = w_X \sum_{i=1}^{n} (\Delta_X^i)^2 + w_Y \sum_{i=1}^{n} (\Delta_Y^i)^2 + w_Z \sum_{i=1}^{n} (\Delta_Z^i)^2.$$

The residuals between the calculated (X_i, Y_i, Z_i) and observed spot centroids are

$$\begin{aligned}
\Delta_X^i &= X_i - X_i' = X_0 + F\mathbf{S}_i \cdot \mathbf{d}_1/\mathbf{S}_i \cdot \mathbf{d}_3 - X_i' \\
\Delta_Y^i &= Y_i - Y_i' = Y_0 + F\mathbf{S}_i \cdot \mathbf{d}_2/\mathbf{S}_i \cdot \mathbf{d}_3 - Y_i' \\
\Delta_Z^i &= Z_i - Z_i' = \varphi_0 + \Delta_\varphi \sum_{j=-\infty}^{\infty} (j - \tfrac{1}{2}) R_j^i - Z_i'.
\end{aligned}$$

Let s_μ ($\mu = 1, \ldots, k$) denote the k independent parameters for which initial estimates are available. Expanding the residuals to first order in the parameter changes δs_μ gives

$$\Delta(s_\mu + \delta s_\mu) \simeq \Delta(s_\mu) + \sum_{\mu=1}^{k} \frac{\partial \Delta}{\partial s_\mu} \delta s_\mu.$$

The parameters should be changed in such a way as to minimize $E(\delta s_\mu)$, which implies $\partial E/\partial \delta s_\mu = 0$ for $\mu = 1, \ldots, k$. The δs_μ are found as the solution of the k normal equations

$$\begin{aligned}
&\sum_{\mu'=1}^{k} \left(w_X \sum_{i=1}^{n} \frac{\partial \Delta_X^i}{\partial s_\mu} \frac{\partial \Delta_X^i}{\partial s_{\mu'}} + w_Y \sum_{i=1}^{n} \frac{\partial \Delta_Y^i}{\partial s_\mu} \frac{\partial \Delta_Y^i}{\partial s_{\mu'}} + w_Z \sum_{i=1}^{n} \frac{\partial \Delta_Z^i}{\partial s_\mu} \frac{\partial \Delta_Z^i}{\partial s_{\mu'}} \right) \delta s_{\mu'} \\
&\quad = -\left(w_X \sum_{i=1}^{n} \Delta_X^i \frac{\partial \Delta_X^i}{\partial s_\mu} + w_Y \sum_{i=1}^{n} \Delta_Y^i \frac{\partial \Delta_Y^i}{\partial s_\mu} + w_Z \sum_{i=1}^{n} \Delta_Z^i \frac{\partial \Delta_Z^i}{\partial s_\mu} \right).
\end{aligned}$$

The parameters are corrected by δs_μ and a new cycle of refinement is started until a minimum of E is reached. The weights

$$w_X = 1/\sum_{i=1}^{n} (\Delta_X^i)^2, \quad w_Y = 1/\sum_{i=1}^{n} (\Delta_Y^i)^2, \quad w_Z = 1/\sum_{i=1}^{n} (\Delta_Z^i)^2$$

are calculated with the current guess for s_μ at the beginning of each cycle.

The derivatives appearing in the normal equations can be worked out from the definitions given in Sections 11.3.2.2 and 11.3.2.4 and only the form of the gradient of the Z residuals is shown. Assuming $\sigma_i = \sigma_M/|\zeta_i|$ ($i = 1, \ldots, n$) is constant for each reflection, the gradients of the Z residuals are obtained from the chain rule and the relation $\mathrm{d}\,\mathrm{erf}(z)/\mathrm{d}z = (2/\pi^{1/2})\exp(-z^2)$.

$$\begin{aligned}
\frac{\partial \Delta_Z^i}{\partial s_\mu} &= \frac{\partial \Delta_Z^i}{\partial \varphi_i} \frac{\partial \varphi_i}{\partial s_\mu} \\
\frac{\partial \Delta_Z^i}{\partial \varphi_i} &= \frac{\Delta_\varphi}{(2\pi)^{1/2} \sigma_i} \sum_{j=-\infty}^{\infty} \exp[-(\varphi_0 + j\Delta_\varphi - \varphi_i)^2 / 2\sigma_i^2] \\
\frac{\partial \varphi_i}{\partial s_\mu} &= \cos \varphi_i \frac{\partial \sin \varphi_i}{\partial s_\mu} - \sin \varphi_i \frac{\partial \cos \varphi_i}{\partial s_\mu}.
\end{aligned}$$

Obviously, $\partial \Delta_Z^i / \partial s_\mu$ is small for a fully recorded reflection because of the small values of all exponentials appearing in $\partial \Delta_Z^i / \partial \varphi_i$. In contrast, the gradient for a partial reflection that is equally recorded on two adjacent images is most sensitive to parameter variations because one of the exponentials assumes its maximum value. In the limiting case of infinitely fine-sliced data it can be shown that $\lim_{\Delta\varphi \to 0} \partial \Delta_Z^i / \partial \varphi_i = 1$. Thus, the refinement scheme based on observed Z centroids, as described here and implemented in *XDS*, is applicable to fine-sliced data and also to data recorded with a large oscillation range.

11.3.3. Integration

Assuming that the diffraction parameters have been refined successfully as described above, the intensity of a reflection is distributed in the neighbourhood of the predicted location of the diffraction peak among detector pixels of one or several adjacent rotation images. Accurate integration requires several steps: determination of a reflection mask, estimation of the background, generation of reference profiles and integration by profile fitting.

The intensity distribution of a reflection can be modelled analytically or derived from the observed profiles of neighbouring strong spots. For the rotation method, the profile shape depends strongly on the specific path of the reflection through the Ewald sphere and on variations in the angle of incidence of the diffracted beam on a flat detector. These geometrical distortions can be eliminated by mapping the reflections onto the coordinate system defined in Section 11.3.2.3, which simplifies the task of modelling the expected intensity distribution as all reflection profiles become similar.

11.3.3.1. Reflection mask

The parameters σ_M and σ_D of the Gaussian model (see Section 11.3.2.3) used to describe reflection shape can be determined automatically from one or more data images by the following procedure.

(i) Identify and mark strong pixels in the data image.
(ii) Assign the indices of the nearest reflection to each strong pixel.
(iii) Sort the strong pixels by the assigned reflection indices such that pixels with the same indices follow each other in the list.
(iv) For each strong reflection find the rectangular box that encloses all of the strong pixels belonging to the reflection.
(v) Increase the box slightly and use all pixels within the box that are not strong for background determination.
(vi) Subtract the background and determine the centroid and variance s^2 of the intensity-weighted diffracted-beam directions $\lambda\mathbf{S}'$ associated with each strong pixel belonging to the spot (see Section 11.3.2.3).
(vii) Reject the spot if the centroid position deviates too much from the calculated spot location.
(viii) Calculate φ and ζ for the accepted reflection and save the three values φ, ζ and s^2 in a list.

The standard deviation of the beam divergence is obtained directly from this list of n reflections as

$$\sigma_D^2 = \frac{1}{n} \sum_{j=1}^{n} s_j^2.$$

Determination of the standard deviation of the reflecting range, the mosaicity σ_M, requires additional considerations. For each of the n reflections from the list above, let τ denote the angular difference between the rotation angle φ at its Bragg maximum and the centre of the oscillation angles covered by the image. The fraction of observed reflection intensity is (see Section 11.3.2.4)

$$R(\tau;\sigma_M/\zeta)=\frac{1}{2\Delta_\varphi}\left[\operatorname{erf}\left(\frac{\tau+\Delta_\varphi/2}{2^{1/2}\sigma_M/\zeta}\right)-\operatorname{erf}\left(\frac{\tau-\Delta_\varphi/2}{2^{1/2}\sigma_M/\zeta}\right)\right].$$

For a given σ_M/ζ the function $R(\tau; \sigma_M/\zeta)$ assumes its maximum at $\tau = 0$ and declines as $|\tau|$ increases. The decline depends strongly on the mosaicity σ_M and on the path length of the reflection through the Ewald sphere, which is accounted for by the factor $1/\zeta$. For a large mosaicity $R(\tau; \sigma_M/\zeta)$ declines slowly, which explains why for such crystals many reflections with large $|\tau|$ values can be observed on a data image. Clearly, the list of strong spots located by the automatic procedure described above contains information about the mosaicity of the crystal. The problem of finding σ_M from this list can be solved if one considers each τ value as a random variable drawn from a probability distribution $R(\tau; \sigma_M/\zeta)$ with population parameter σ_M/ζ. The mosaicity σ_M can then be estimated so that it maximizes the likelihood (joint probability)

$$L(\sigma_M)=R(\tau_1;\sigma_M/\zeta_1)\cdot R(\tau_2;\sigma_M/\zeta_2)\ldots R(\tau_n;\sigma_M/\zeta_n).$$

The parameters σ_D and σ_M are mainly used to specify the integration region around the spot defined by the parameters δ_M and δ_D, which are typically chosen to be 6–10 times larger than σ_M and σ_D, respectively (see Section 11.3.2.1). The reflection mask thus comprises all image pixels that satisfy

$$|\varepsilon_1|\le\delta_D/2,\quad |\varepsilon_2|\le\delta_D/2,\quad |\varepsilon_3|\le\delta_M/2$$

when mapped to the profile coordinate system $\{\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3\}$ defined in Section 11.3.2.3. In addition, pixels are excluded from the mask if they are closer to the predicted Bragg peak of an intruding reflection from the neighbourhood.

11.3.3.2. Background

The region around a spot is assumed to have been chosen to be large enough to include a sufficient number of pixels which can be used for determination of the background. Background determination, as implemented in *XDS*, begins by sorting all pixels belonging to a reflection by increasing intensity. For weak or absent reflections, these values should represent a random sample drawn from a normal distribution. If this is not the case, the pixel with the largest intensity is removed until the sampling distribution of the remaining smaller items satisfies the expected distribution. This method will also exclude pixels with unexpected high values, such as ice reflections. The background, determined as the mean value of the accepted pixels, is systematically overestimated for strong spots because of some residual intensity extending into the accepted background pixels. This residual intensity is estimated from the expected distribution $\omega(\varepsilon_1, \varepsilon_2, \varepsilon_3)$ defined in Section 11.3.2.3 and removed from the final background value.

11.3.3.3. Standard profiles

Reflection profiles are represented on the Ewald sphere within a domain D_0 comprising $2n_1 + 1$, $2n_2 + 1$ and $2n_3 + 1$ equidistant gridpoints along $\mathbf{e}_1$, $\mathbf{e}_2$ and $\mathbf{e}_3$, respectively. The sampling distances between adjacent grid points are then $\Delta_1 = \delta_D/(2n_1 + 1)$, $\Delta_2 = \delta_D/(2n_2 + 1)$ and $\Delta_3 = \delta_M/(2n_3 + 1)$. Thus, grid coordinate ν_3 ($\nu_3 = -n_3, \ldots, n_3$) covers the set of rotation angles

$$\Gamma_{\nu_3}=\{\varphi'|(\nu_3-\tfrac{1}{2})\Delta_3\le(\varphi'-\varphi)\cdot\zeta\le(\nu_3+\tfrac{1}{2})\Delta_3\}.$$

Contributions to the spot intensity come from one or several adjacent data images ($j = j_1, \ldots, j_2$), each covering the set of rotation angles

$$\Gamma_j=\{\varphi'|\varphi_0+(j-1)\Delta_\varphi\le\varphi'\le\varphi_0+j\Delta_\varphi\}.$$

Assuming Gaussian profiles along $\mathbf{e}_3$ for all reflections (see Section 11.3.2.3), the fraction of counts (after subtraction of the background) contributed by data frame j to grid coordinate ν_3 is

$$f_{\nu_3 j}\simeq\frac{\int_{\Gamma_j\cap\Gamma_{\nu_3}}\exp[-(\varphi'-\varphi)^2/2\sigma^2]\,\mathrm{d}\varphi'}{\int_{\Gamma_j}\exp[-(\varphi'-\varphi)^2/2\sigma^2]\,\mathrm{d}\varphi',}$$

where $\sigma = \sigma_M/|\zeta|$. The integrals can be expressed in terms of the error function, for which efficient numerical approximations are available (Abramowitz & Stegun, 1972). Finally, each pixel in data image j belonging to the reflection is subdivided into 5 × 5 areas of equal size and $f_{\nu_3 j}/25$ of the pixel signal is added to the profile value at grid coordinates ν_1, ν_3, ν_3 corresponding to each subdivision.

This complicated procedure leads to more uniform intensity profiles for all reflections than using their untransformed shape. This simplifies the task of modelling the expected intensity distribution needed for integration by profile fitting. As implemented in *XDS*, reference profiles are learnt every 5° of crystal rotation at nine positions on the detector, each covering an equal area of the detector face. In the learning phase, profile boxes of the strong reflections are normalized and added to their nearest reference profile boxes. The contributions are weighted according to the distance from the location of the reference profile. Each grid point within the average profile boxes is classified as signal if it is above 2% of the peak maximum. Finally, each profile is scaled such that the sum of its signal pixels normalizes to one. The analytical expression $\omega(\varepsilon_1, \varepsilon_2, \varepsilon_3)$ defined in Section 11.3.2.3 for the expected intensity distribution is only a rough initial approximation, which is now replaced by the empirical reference profiles.

11.3.3.4. Intensity estimation

If an expected intensity distribution $\{p_i|i \in D_0\}$ of the observed profile is given in a domain D_0, the reflection intensity I can be estimated as

$$I=\frac{\sum_{i\in D}(c_i-b_i)p_i/v_i}{\sum_{i\in D}p_i^2/v_i},$$

which minimizes the function

$$\psi(I)=\sum_{i\in D}(c_i-I\cdot p_i-b_i)^2/v_i,\quad \sum_{i\in D_0}p_i=1.$$

b_i, c_i, v_i ($i \in D$) are the background, contents and variance of pixels observed in a subdomain $D \subseteq D_0$ of the expected distribution. The background b_i underneath a diffraction spot is often assumed to be a constant which is estimated from the neighbourhood around the reflection. Determination of reflection intensities by profile fitting has a long tradition (Diamond, 1969; Ford, 1974; Kabsch, 1988*b*; Otwinowski, 1993). Implementations of the method differ mainly in their assumptions about the variances v_i. Ford used constant variances, which work well for films, which have a high intrinsic background. In *XDS*, which was originally designed for a multwire detector, $v_i \propto p_i$ was assumed, which results in a straight summation of background-subtracted counts within the expected profile region, $I = \sum_{i\in D}(c_i - b_i)/\sum_{i\in D} p_i$. This particular simple formula is very satisfactory for the low background typical of these detectors. For the general case, however, better results can be obtained by using $v_i = b_i + Ip_i$ for the pixel variances as shown by Otwinowski and implemented in *DENZO* and in later versions of *XDS*. Starting with $v_i = b_i$, the intensity is now found by an iterative process which is terminated if the new intensity estimate becomes negative or does not change within a small tolerance, which is usually reached after three cycles. It can be shown that the solution thus obtained is unique.

11.3.4. Scaling

The integrated intensities of the reflections need to be corrected by various factors arising from the following:

(i) changes in the intensity of the incident beam and variations in the illuminated crystal volume,
(ii) absorption of incident and diffracted beams,
(iii) radiation damage,
(iv) variations in detector sensitivity within the detector plane, and
(v) different crystal sizes and crystalline order if the data are from several crystals.

The combined effect manifests itself in correlations of the intensity of a reflection with details of its measurement, such as time (or image number) and location in the detector plane. Usually, many statistically independent observations of symmetry-related reflections are recorded in the rotation images taken from one or several similar crystals of the same compound. The squared structure-factor amplitudes of equivalent reflections should be equal and many scaling procedures (see, for example Evans, 2006; Otwinowski *et al.*, 2003; Kabsch, 1988*b*) exploit this *a priori* knowledge to determine a correction factor for each observed intensity. However, the scaling programs differ in the details of their scaling models, *i.e.* the parameterization and methods used for determination of the correction factors. Below, the approach is described as implemented recently in the programs *XDS* and *XSCALE* (Chapter 11.6).

If more than one data set is included, these are first put on approximately the same scale by the factor $K{\cdot}\exp[B{\cdot}(2\sin\theta/\lambda^2)]$ involving two parameters, K and B, for each data set. The parameter values are assigned so that the resulting correction factors fit best to the observed intensity ratios of common reflections in each pair of data sets.

For the more detailed corrections, three types of two-dimensional functions are used in succession to remove correlations of the intensity of a reflection with (i) image number and resolution, (ii) location in the detector plane and (iii) image number and 13 detector surface regions. To correct for non-uniform detector response such as edge effects at the boundaries of multisegment detectors, the use of smooth analytical correction functions was avoided. Instead, the correction functions are sampled at a finite set of grid regions covering all of the function's definition range. The grid regions are chosen automatically to be as small as possible without overfitting the data so that each sampling region contains more than a specified minimum number of reflections (default 50). Thus, the correction function G is represented by a possibly large number of reciprocal factors G_l, where the subscript l denotes the grid regions.

The correction factors G_l are found in a cyclic prodedure starting with $G_l = 1$. In each cycle, G_l is updated by a factor g_l. The target function for refinement is based on an observational equation for each reflection,

$$\psi_{hl} = (I_{hl} - g_l G_l I_h)/\sigma_{hl},$$

as introduced by Hamilton *et al.* (1965). The subscript h represents the unique reflection indices and hl denotes symmetry-related reflections to h that need to be corrected by the reciprocal scaling factor g_l associated with grid point l; I_{hl} and σ_{hl} are their weighted mean and standard deviation, respectively. This standard deviation is considered to be infinitely large if no such reflection was measured, which amounts to omitting the observational equation altogether. The factors g_l and the 'true' intensities I_h are found at the minimum of the function

$$\Psi = \sum_{hl} \psi_{hl}^2 + \sum_l (g_l G_l - 1)^2/\sigma^2.$$

The first sum on the right side is a homogeneous function of g_l of degree zero so that the g_l would only be determined up to an arbitrary factor. The second sum on the right side is used to weakly restrain the scaling factors to one; a reasonable value is $\sigma = 0.05$. Minimization of Ψ leads to updates g_l in terms of the 'true' intensities I_h which again depend on g_l,

$$\begin{aligned} g_l &= \frac{\sum_h I_h (I_{hl}/G_l)/(\sigma_{hl}/G_l)^2 + G_l/\sigma^2}{\sum_h I_h^2/(\sigma_{hl}/G_l)^2 + G_l^2/\sigma^2} \\ I_h &= \frac{\sum_l g_l (I_{hl}/G_l)/(\sigma_{hl}/G_l)^2}{\sum_l g_l^2/(\sigma_{hl}/G_l)^2} \\ I_h^o &= \frac{\sum_l (I_{hl}/G_l)/(\sigma_{hl}/G_l)^2}{\sum_l 1/(\sigma_{hl}/G_l)^2}. \end{aligned}$$

The new update factors g_l are obtained by using 'true' intensities I_h^o from the previous cycle instead of the current I_h as defined above. At the end of the cycle, the old correction factors G_l are updated by multiplication with the new g_l. This cyclic procedure typically converges in less than six cycles.

The approach described here has been implemented in *XDS* and *XSCALE* and has been successfully used for more than two years. In contrast to the 'shortest path' eigenvector method of Fox & Holmes (1966), which is very efficient for a relatively small number of variables, the computations here require a time that is proportional to the number of reflections used for scaling and thus quickly lead to a solution even when a very large number of correction factors from many data sets are involved.

A recent literature search revealed that the above method of alternating optimization steps for the intensities and scaling factors is essentially the method of Monahan *et al.* (1967). Their original work was largely neglected, presumably because of the lack of convergence of the iterations in some test cases. Apparently, the preliminary scaling step in *XSCALE* is essential for convergence. A detailed mathematical analysis of the alternate convex search method has been carried out (Junk *et al.*, 2011).

11.3.5. Post refinement

The number of fully recorded reflections on each single image rapidly declines for small oscillation ranges and the complete intensities of the partially recorded reflections have to be estimated. This presented a serious obstacle in early structural work on virus crystals, as the crystal had to be replaced after each exposure on account of radiation damage. A solution to this problem, the 'post-refinement' technique, was found by Schutt, Winkler and Harrison and variants of this powerful method have been incorporated into most data-reduction programs (for a detailed discussion, see Harrison *et al.*, 1985; Rossmann, 1985). The method derives complete intensities of reflections that are only partially recorded on an image from accurate estimates for the fractions of observed intensity: the 'partiality'. The partiality of each reflection can always be calculated as a function of orientation, unit-cell metric, mosaic spread of the crystal and model intensity distributions. The accuracy of the estimated full reflection intensity obviously then strongly depends on a precise knowledge of the parameters describing the diffraction experiment. Usually, symmetry-related fully recorded reflections can be found for many of the partial reflections and the list of such pairs of intensity observations can be used to refine the required parameters using a least-squares procedure. Clearly, this refinement is carried out after all images have been processed, which explains why the procedure is called 'post refinement'.

Adjustments of the diffraction parameters s_μ ($\mu = 1, \ldots, k$) are determined by minimization of the function E, which is defined as the weighted sum of squared residuals between calculated and observed partial intensites.

$$\begin{aligned} E &= \sum_{hj} w_{hj}(\Delta_{hj})^2 \\ \Delta_{hj} &= R_j(\varphi_{hj})g_j I_h - I_{hj} \\ w_{hj} &= 1/\{\sigma^2(I_{hj}) + [R_j(\varphi_{hj})g_j]^2\sigma^2(I_h)\}. \end{aligned}$$

Here, I_{hj} is the intensity recorded on image j of a partial reflection with indices summarized as hj, I_h is the mean of the observed intensities of all fully recorded reflections symmetry-equivalent to hj, g_j is the inverse scaling factor of image j, φ_{hj} is the calculated spindle angle of reflection hj at diffraction and R_j is the computed fraction of total intensity recorded on image j.

Expansion of the residuals Δ_{hj} to first order in the parameter changes δs_μ and minimization of $E(\delta s_\mu)$ leads to the k normal equations

$$\sum_{\mu'=1}^{k}\left(\sum_{hj} w_{hj}\frac{\partial\Delta_{hj}}{\partial s_\mu}\frac{\partial\Delta_{hj}}{\partial s_{\mu'}}\right)\delta s_{\mu'} = -\sum_{hj} w_{hj}\Delta_{hj}\frac{\partial\Delta_{hj}}{\partial s_\mu}.$$

Often, the normal matrix is ill-conditioned since changes in some unit-cell parameters or small rotations of the crystal about the incident X-ray beam do not significantly affect the calculated partiality R_j. To take care of these difficulties, the system of equations is rescaled to yield unit diagonal elements for the normal matrix and the correction vector δs_μ is filtered by projection into a subspace defined by the eigenvectors of the normal matrix with sufficiently large eigenvalues (Diamond, 1966).

The parameters are corrected by the filtered δs_μ and a new cycle of refinement is started until a minimum of E is reached. The weights, residuals and their gradients are calculated using the current values for s_μ and g_j at the beginning of each cycle. The derivatives

$$\frac{\partial\Delta_{hj}}{\partial s_\mu} = g_j I_h\left(\frac{\partial R_j}{\partial\varphi_{hj}}\frac{\partial\varphi_{hj}}{\partial s_\mu} + \frac{\partial R_j}{\partial\sigma_{\rm M}}\frac{\partial\sigma_{\rm M}}{\partial s_\mu} + \frac{\partial R_j}{\partial|\zeta_{hj}|}\frac{\partial|\zeta_{hj}|}{\partial s_\mu}\right)$$

appearing in the normal equations can be worked out from the definitions given in Sections 11.3.2.2 and 11.3.2.4 (to simplify the following equations, the subscript hj is omitted). The fraction R_j of total intensity can be expressed in terms of the error function (see Section 11.3.2.4) as

$$\begin{aligned} R_j &= [\mathrm{erf}(z_1) - \mathrm{erf}(z_2)]/2 \\ z_1 &= |\zeta|(\varphi_0 + j\Delta_\varphi - \varphi)/2^{1/2}\sigma_M \\ z_2 &= |\zeta|[\varphi_0 + (j-1)\Delta_\varphi - \varphi]/2^{1/2}\sigma_M. \end{aligned}$$

Using the relation $\mathrm{d}\,\mathrm{erf}(z)/\mathrm{d}z = (2/\pi^{1/2})\exp(-z^2)$, the derivatives of R_j are

$$\begin{aligned} \frac{\partial R_j}{\partial\varphi} &= [\exp(-z_2^2) - \exp(-z_1^2)]|\zeta|/[\sigma_M(2\pi)^{1/2}] \\ \frac{\partial R_j}{\partial\sigma_M} &= [z_2\exp(-z_2^2) - z_1\exp(-z_1^2)]/(\sigma_M\pi^{1/2}) \\ \frac{\partial R_j}{\partial|\zeta|} &= [z_1\exp(-z_1^2) - z_2\exp(-z_2^2)]/(|\zeta|\pi^{1/2}). \end{aligned}$$

The derivatives $\partial\varphi/\partial s_\mu$, $\partial\sigma_M/\partial s_\mu$ and $\partial|\zeta|/\partial s_\mu$ remain to be worked out (not shown here). As discussed in detail by Greenhough & Helliwell (1982), spectral dispersion and asymmetric beam crossfire lead to some variation in σ_M, which makes it necessary to include additional parameters in the list s_μ. The effect of these parameters on the partiality is dealt with easily by the derivatives $\partial\sigma_M/\partial s_\mu$.

The refinement scheme described above requires initial scaling factors g_j. With the now improved estimates for the partialities R_j, a new set of scaling factors can be obtained using the method outlined in Section 11.3.4. This alternating procedure of scaling and post refinement usually converges within three cycles.

The use of error functions for modelling partiality, as implicated by a Gaussian model for describing spot shape, was chosen here for reasons of conceptual simplicity and coherence. This choice is unlikely to significantly alter the results of post refinement that are based on other functions of similar form (see the discussion by Rossmann, 1985).

11.3.6. Space-group assignment

Identification of the correct space group is not always an easy task and should be postponed for as long as possible. Sometimes, the true space group only becomes known when the structure has been successfully solved and refined! However, one can expect to identify a small number of possibilities from the diffraction experiment.

Fortunately, all data processing as implemented in the program *XDS* can be carried out in the absence of any knowledge of the crystal symmetry and unit-cell parameters. In this case, a reduced cell is extracted from the observed diffraction pattern and processing of the data images continues to completion as if the crystal were triclinic. Clearly, the reflection indices then refer to the reduced cell and must be reindexed once the space group is known. For all space groups, the required reindexing transformation is linear and involves only whole numbers, as shown in Part 9 of Volume A of *International Tables for Crystallography* (2005).

Automatic space-group assignment is carried out in two steps once integrated intensities of all reflections are available (see Chapter 11.6). Firstly, the Bravais lattices are identified that are compatible with the reduced cell derived from the observed diffraction pattern. In the second step, all enantiomorphous space groups compatible with the observed lattice symmetry are rated by a redundancy-independent R factor. The group is selected that explains all integrated intensities in the data set at an acceptable R factor requiring a minimum number of unique reflections (Occam's principle). This approach deliberately avoids any test for the presence of screw axes as these tests would depend strongly on the completeness of the data. Fortunately, the presence or absence of screw axes is irrelevant for the determination of data correction/scaling factors (see Section 11.3.4).

Table 11.3.6.1

Rating of lattice types implied by a given reduced cell

11.3.6.1. Determination of the Bravais lattice

The determination of possible Bravais lattices is based upon the concept of the reduced cell whose metric parameters characterize 44 lattice types as described in Part 9 of Volume A of *International Tables for Crystallography* (2005). A primitive basis $\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3$ of a given lattice is defined there as a reduced cell if it is right-handed and if the components of its metric tensor

$$A = \mathbf{b}_1 \cdot \mathbf{b}_1, \quad B = \mathbf{b}_2 \cdot \mathbf{b}_2, \quad C = \mathbf{b}_3 \cdot \mathbf{b}_3$$
$$D = \mathbf{b}_2 \cdot \mathbf{b}_3, \quad E = \mathbf{b}_1 \cdot \mathbf{b}_3, \quad F = \mathbf{b}_1 \cdot \mathbf{b}_2$$

satisfy a number of conditions (inequalities). The main conditions state that the basis vectors are the shortest three linear independent lattice vectors with either all acute or all non-acute angles between them. As specified in *International Tables for Crystallography*, each of the 44 lattice types is characterized by additional equality relations among the six components of the reduced-cell metric tensor. As an example, for lattice character 11 (Bravais type *tP*) the components of the metric tensor of the reduced cell must satisfy

$$A = B, \quad B \leq C, \quad D = 0, \quad E = 0, \quad F = 0.$$

(Note that the other tetragonal primitive lattice character 21 requires $A \leq B = C$ with the fourfold as the shortest axis.)

Any primitive triclinic cell describing a given lattice can be converted into a reduced cell. It is well known, however, that the reduced cell thus derived is sensitive to experimental error. Hence, the direct approach of first deriving the correct reduced cell and then finding the lattice type is unstable and may in certain cases even prevent identification of the correct Bravais lattice.

A suitable solution of the problem has been found that avoids any decision as to what the 'true' reduced cell is (see Kabsch, 1993). The essential ingredients of this procedure are (i) a database of possible reduced cells and (ii) a backward-search strategy that finds the best-fitting cell in the database for each lattice type.

The database is derived from a seed cell which strictly satisfies the definitions for a reduced cell. All cells of the same volume as the seed cell whose basis vectors can be linearly expressed in terms of the seed vectors by indices −1, 0 or +1 are included in the database. Each unit cell in the database is considered as a potential reduced cell, although some of the defining conditions as given in Part 9 of Volume A of *International Tables for Crystallography* (2005) may be violated. These violations are treated as arising from experimental error.

The backward-search strategy starts with the hypothesis that the lattice type is already known and identifies the best-fitting cell in the database of possible reduced cells. In contrast to a forward-directed search, it is now always possible to decide which conditions have to be satisfied by the components of the metric tensor of the reduced cell. The total amount by which all these equality and inequality conditions are violated is used as a quality index. For example, to find out how well a potential reduced cell $\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3$ from the database characterizes lattice character 11 (Bravais lattice *tP*), the quality index

$$p_{11}(\mathbf{b}_1, \mathbf{b}_2, \mathbf{b}_3) = |A - B| + \max(0, B - C) + |D| + |E| + |F|$$

is computed. Positive values of p_{11} indicate that some conditions are not satisfied. All potential reduced cells in the database are tested and the smallest value for p_{11} is used for rating lattice type 11. A similar test is carried out for all 44 possible lattice types using quality indices based on their defining conditions as listed in Part 9 of Volume *A* of *International Tables for Crystallography* (2005).

The results obtained using this method are shown in Table 11.3.6.1 for the example of a data set comprising 177 images with each exposure covering 0.5° of spindle rotation. The space group of the protein crystal was $P4_32_12$ (unit-cell parameters a = 159.4, b = 159.4, c = 160.3 Å), but this knowledge was not used in the processing. Instead, the data were processed with respect to a triclinic reduced cell derived from the observed diffraction pattern as described above. The images contained a total of 292 998 reflections within the resolution range 20.0–3.0 Å; 57 548 reflections in the resolution range 10.0–5.0 Å were used for space-group determination. For determination of the lattice symmetry all 44 possibilities were considered and rated by their quality index. The table shows the possible lattice symmetries, their implied conventional unit-cell parameters and a reindexing transformation. The table entries are sorted by increasing quality index and reveal a nearly cubic lattice symmetry. A lattice symmetry is considered to be acceptable if it has a low quality

Table 11.3.6.2
Identification of possible space groups

146	$R3$	4	hR	61.1	16751	40797	225.9	225.9	276.2	90.0	90.0	120.0

index and its implied unit-cell parameters do not violate the ideal values by more than 3.0° in angles and 3% in cell axes. Thus, except for the last entry, all of the lattice symmetries in the table are acceptable; the correct lattice type 11 *tP* is highlighted. Lattice symmetries that are not accepted include all body-centred lattices or those that are centred on all faces; they are omitted from the table.

The reindexing transformation REIDX() consists of 12 integers that relate the original indices h, k, l used during the integration to the indices h', k', l' with respect to the new cell.

$$\begin{aligned} h' &= \frac{[\text{REIDX}(1)\times h + \text{REIDX}(2)\times k + \text{REIDX}(3)\times l]}{\text{IDXV}} \\ &\quad + \text{REIDX}(4) \\ k' &= \frac{[\text{REIDX}(5)\times h + \text{REIDX}(6)\times k + \text{REIDX}(7)\times l]}{\text{IDXV}} \\ &\quad + \text{REIDX}(8) \\ l' &= \frac{[\text{REIDX}(9)\times h + \text{REIDX}(10)\times k + \text{REIDX}(11)\times l]}{\text{IDXV}} \\ &\quad + \text{REIDX}(12). \end{aligned}$$

The value of the integer IDXV depends on the lattice type used for specifying reflection indices in the integration step. IDXV is 1 for a primitive lattice, 2 for a face-centred or body-centred lattice, 3 for a rhombohedral lattice and 4 for a lattice centred on all faces. In the example case we have IDXV = 1 because integration was carried out in space group $P1$.

Note also that elements 4, 8 and 12 of the transformation are always 0 in this example. These three extra elements were introduced to provide a simple tool for correcting the indices if all reflections are misindexed by a constant.

11.3.6.2. Finding possible space groups

For protein crystals, the absence of parity-changing symmetry operators restricts the number of possible space groups to 65 instead of 230. Moreover, the determination of correction factors for the integrated intensities does not depend on the presence or absence of any screw axes so that data processing can be finished without this knowledge. This reduces the problem to the identification of an enantiomorphous space group without screw axes that is compatible with the observed lattice symmetry (see above).

For solution of the problem, a quality indicator of the mean variation in the intensities of symmetry-equivalent reflections (R_{meas}) is calculated for each possible group. The decision for a particular group is then based on Occam's principle: the selected group must explain all integrated intensities in the data set at acceptable quality, thereby requiring a minimum number of unique reflections.

A suitable redundancy-independent data quality indicator has been suggested by Diederichs & Karplus (1997) and Weiss (2001),

$$R_{\text{meas}} \equiv R_{\text{r.i.m.}} = \frac{\sum_{hl}\left[n_h/(n_h-1)\right]^{1/2}|I_{hl}-I_h|}{\sum_{hl} I_{hl}}.$$

The subscript h represents the unique reflection indices and hl denotes any of the n_h symmetry-related reflections to h. The absolute differences between the observed intensities I_{hl} and their mean intensity I_h are weighted to remove any dependency on n_h and compared with the intensities. Small values of R_{meas} indicate accurate single observations I_{hl} and the use of symmetry operators compatible with the intensity data set.

For the above example data set, Table 11.3.6.2 lists all enantiomorphous groups which are in harmony with the observed lattice symmetry shown in Table 11.3.6.1. For each listed space group, UNIQUE is the number of unique reflections and COMPARED is the number of reflections used to calculate the redundancy-independent R factor R_{meas}. Two sets of groups can be distinguished clearly: those implying an acceptable R_{meas} and a second set with $R_{\text{meas}} > 45\%$, which is totally unacceptable. Among the acceptable solutions a minimum number of unique reflections is needed if the crystal has the tetragonal space-group symmetry $P422$.

This chapter is based on a recent article published in *Acta Crystallographica Section D* (Kabsch, 2010).

Chapter 11.4. *DENZO* and *SCALEPACK*

Z. Otwinowski, W. Minor, D. Borek and M. Cymborowski

11.4.1. Introduction

X-ray diffraction data analysis, as performed by the *HKL* package (Otwinowski, 1993; Otwinowski & Minor, 1997) or similar programs (Rossmann, 1979; Leslie & Tsukihara, 1980; Howard *et al.*, 1985; Blum *et al.*, 1987; Bricogne, 1987; Howard *et al.*, 1987; Messerschmidt & Pflugrath, 1987; Kabsch, 1988; Higashi, 1990; Sakabe, 1991), is used to obtain the following results:

(1) estimates of structure-factor amplitudes and determination of the crystal symmetry;
(2) estimates of the crystal unit-cell parameters;
(3) estimates of the errors of structure-factor amplitudes and unit-cell parameters;
(4) detector calibration; and
(5) detection of hardware malfunctions.

Other results, such as the indexing of diffraction patterns, are in most cases only intermediate steps in the process of reaching the above goals. The *HKL* system and other programs have tools to validate these intermediate results by self-consistency checks.

The fundamental stages of data analysis are:

(1) inspection of the diffraction images;
(2) (auto)indexing;
(3) refinement of parameters describing diffraction geometry;
(4) integration of the diffraction peaks;
(5) conversion of the diffraction-peak intensities to a common scale;
(6) determination of the diffraction-pattern symmetry and merging of symmetry-related reflections; and
(7) assessment of structural and phasing signals, summary statistics and estimation of errors.

The order of these stages represents the natural flow of data reduction, but quite often these steps are repeated iteratively to introduce information gained at a later stage.

The three basic questions in collecting diffraction data are:

(1) *whether to collect data from a particular sample*;
(2) *what range of data to collect*; and
(3) *how to collect and analyse the data.*

These questions and steps (1)–(7) of data analysis are intimately intertwined.

Data analysis makes specific assumptions which the collected data should satisfy. However, the experimenter can verify whether the data satisfy those assumptions only by data analysis. This circular logic can be broken by an iterative process. Data analysis in real time provides immediate feedback during data collection and can remove the guesswork about *whether*, *what* and *how* from the process. The description of data analysis and algorithms that follows will make frequent references to the assumptions about the data and offer guidelines on how to make the experiment fulfil these assumptions.

This article uses the *HKL* package coordinate system to describe data algorithms and analysis. However, as most equations are written in vector notation, they can be easily adapted to conventions used in other programs.

11.4.2. Diffraction from a perfect crystal lattice

X-ray photons can scatter from individual electrons by inelastic and incoherent processes. The coherent scattering by the whole crystal is called diffraction.[1] Energy conservation, when expressed in photon momentum vectors, is equivalent to

$$\mathbf{S}\cdot\mathbf{S}_0 = \tfrac{1}{2}\mathbf{S}\cdot\mathbf{S}, \qquad (11.4.2.1)$$

where $\mathbf{S}$ is the diffraction vector, defined as the change of photon momentum in the scattering process, and $\mathbf{S}_0$ is the incident-beam vector, which is oriented in the direction of the beam and has length $1/\lambda$. Diffraction from a perfect crystal lattice occurs when scattering from all repeating crystal elements is in phase, which can be stated in vector algebra as

$$\mathbf{S}\cdot\mathbf{a} = h, \qquad (11.4.2.2)$$

$$\mathbf{S}\cdot\mathbf{b} = k, \qquad (11.4.2.3)$$

$$\mathbf{S}\cdot\mathbf{c} = l, \qquad (11.4.2.4)$$

where h, k, l are integers called Miller indices and $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are the real-space crystal periodicity vectors, defining the orientation matrix:

$$[\mathbf{A}] = \begin{pmatrix} a_x & a_y & a_z \\ b_x & b_y & b_z \\ c_x & c_y & c_z \end{pmatrix}.$$

In shorter notation, equations (11.4.2.2)–(11.4.2.4) may be written as $\mathbf{h} = [\mathbf{A}]\mathbf{S}$, which in reciprocal space is equivalent to $\mathbf{S} = [\mathbf{A}]^{-1}\mathbf{h}$, with the orientation matrix defined as the inverse of $[\mathbf{A}]$.

The condition for crystal diffraction with Miller indices h, k, l is the existence of a (unique) vector $\mathbf{S}$ which is a solution to equations (11.4.2.1)–(11.4.2.4). Equation (11.4.2.1) states the diffraction condition for vector $\mathbf{S}$. The space of the solutions to equations (11.4.2.2)–(11.4.2.4) is called reciprocal space, and vector $\mathbf{S}$ belongs to this space. However, the following presentation does not depend on the properties of reciprocal space. The laboratory coordinate system used here has its origin at the position of the crystal. A diffraction peak at the detector position in three-dimensional laboratory space $\mathbf{X} = \{x, y, z\}$ corresponds to vector $\mathbf{S}$:

$$\mathbf{S} = \mathbf{X}/\lambda|\mathbf{X}| + \mathbf{S}_0. \qquad (11.4.2.5)$$

Rotation of the crystal around the goniostat axes can be described by vectors $\mathbf{a}, \mathbf{b}, \mathbf{c}$ [equations (11.4.2.2)–(11.4.2.4)] as a function of the goniostat angles $\varphi_1, \varphi_2, \varphi_3$:

$$\mathbf{a} = [\mathbf{R}_1(\varphi_1)][\mathbf{R}_2(\varphi_2)][\mathbf{R}_3(\varphi_3)]\mathbf{a}_0, \qquad (11.4.2.6)$$

where the vectors $\mathbf{a}_0, \mathbf{b}_0, \mathbf{c}_0$ represent the crystal orientation at the zero position of the goniostat. These rotations can be described as (Bricogne, 1987)

---

[1] Owing to the large difference in mass between the crystal and the photon, the energy of the photon is virtually unchanged.

Copyright © 2012 International Union of Crystallography

$$[\mathbf{R}(\varphi)] = \cos(\varphi)\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} + [1-\cos(\varphi)]\begin{pmatrix} e_x e_x & e_x e_y & e_x e_z \\ e_x e_y & e_y e_y & e_y e_z \\ e_x e_z & e_z e_y & e_z e_z \end{pmatrix}$$
$$+ \sin(\varphi)\begin{pmatrix} 0 & -e_z & e_y \\ e_z & 0 & -e_x \\ -e_y & e_x & 0 \end{pmatrix}, \qquad (11.4.2.7)$$

where the values e_x, e_y, e_z represent the direction cosines of a rotation axis. To complete the description of the diffraction geometry, we need a function $\mathbf{X}(p, q)$, describing the position in experimental space of each pixel of the detector with integer coordinates $\{p, q\}$. This function is detector-specific and includes the description of the detector geometry and distortion. For a planar detector

$$\mathbf{X}(p, q) = [\mathbf{R}_x][\mathbf{R}_y][\mathbf{R}_z]\big([\mathbf{R}_{2\theta}]([\mathbf{L}](\mathbf{K}[\mathbf{D}(p, q)] - \mathbf{B}) + \mathbf{T}_D) - \mathbf{T}_D\big)$$
$$+ \mathbf{T}_D, \qquad (11.4.2.8)$$

where $\mathbf{R}_x$, $\mathbf{R}_y$, $\mathbf{R}_z$ are matrices describing the detector's departure from a nominal orientation, $\mathbf{R}_{2\theta}$ is the rotation around the 2θ axis, $\mathbf{T}_D$ is the translation between the detector and the crystal, $\mathbf{L}$ is an operator describing one of the eight possible axis-direction conventions used by the detector manufacturer, $\mathbf{K}$ is an operator scaling pixels to millimetres, $\mathbf{D}$ is a detector-specific distortion function, and $\mathbf{B}$ is the beam position on the detector surface.

Equations (11.4.2.1)–(11.4.2.8) define the necessary and sufficient conditions needed to fully describe both the existence and position on the detector of the diffraction peaks, and provide all information needed to perform autoindexing.

11.4.3. Autoindexing

Among the autoindexing algorithms that have been proposed (Vriend & Rossmann, 1987; Kabsch, 1988; Kim, 1989; Higashi, 1990; Leslie, 1993), the method based on periodicity of the reciprocal lattice tends to be the most reliable (Otwinowski & Minor, 1997; Steller *et al.*, 1997).

Autoindexing starts with a peak search, which results in a set of $\{p, q, i\}$ triplets, where i is the number of the image in which the peak with position $\{p, q\}$ was found. For any given rotation matrix $\mathbf{R}$

$$([\mathbf{R}]\mathbf{S}) \cdot ([\mathbf{R}]\mathbf{a}) = \mathbf{S} \cdot \mathbf{a}, \qquad (11.4.3.1)$$

where $\mathbf{R}$ is defined as

$$[\mathbf{R}] = \big[\mathbf{R}_3(-\varphi_3)\big]\big[\mathbf{R}_2(-\varphi_2)\big]\big[\mathbf{R}_1(-\varphi_1)\big]. \qquad (11.4.3.2)$$

When equation (11.4.3.1) is applied to equation (11.4.2.2), it results in

$$([\mathbf{R}]\mathbf{S}) \cdot \mathbf{a}_o = h, \qquad (11.4.3.3)$$

where $\mathbf{a}_o$ is a three-dimensional vector with as yet unknown components. Note that the matrix $[\mathbf{R}]$ represents crystal rotation when the crystal is in the diffraction condition defined by the existence of the solution to equations (11.4.2.1)–(11.4.2.4), described by vector $\mathbf{S}$. For data collected in wide oscillation mode,[2] the angle at which diffraction occurs is not known *a priori*; however, it can be approximated by the middle of the oscillation range of the image. Combining the peak position $\{p, q\}$ with equations (11.4.2.5) and (11.4.2.8) provides an estimate of the vector $\mathbf{S}$. Therefore, equation (11.4.3.3) and similar equations for the k and l Miller indices are approximately satisfied, given approximation and experimental errors. The purpose of autoindexing is to determine the unknown vectors $\mathbf{a}_0$, $\mathbf{b}_0$, $\mathbf{c}_0$ and the $\{h, k, l\}$ triplet for each diffraction peak. To accomplish this, three equations for each peak [equation (11.4.3.3) and the analogous equations for k and l] must be solved. *DENZO* introduced a method based on the observation that the maxima of the function

$$\sum_i \cos\big[2\pi([\mathbf{R}]\mathbf{S}_i) \cdot \mathbf{a}_0\big] \qquad (11.4.3.4)$$

are the approximate solutions to this set of equations. To speed up the search for all significant maxima, a two-step process is used. The first step is the search for maxima of function (11.4.3.4) on a three-dimensional uniform grid, made very fast owing to the use of a fast Fourier transform (FFT) to evaluate function (11.4.3.4). Function (11.4.3.4) is identical to structure-factor calculations in the space group $P1$, which allows the use of the crystallographic FFT. Because the maxima at the grid points (*HKL* uses a 128 × 128 × 128 grid) only approximate the maxima of function (11.4.3.4), the vectors resulting from a grid search are optimized by Newton's method. Function (11.4.3.4) has maxima not only for basic periodic vectors $\mathbf{a}_0$, $\mathbf{b}_0$ and $\mathbf{c}_0$, but also for any integer linear combination of them. Any set of three such vectors with a minimal nonzero determinant can be used to describe the crystal lattice. Steller *et al.* (1997) describe the algorithm that finds the most reliable set of three vectors. This set needs to be converted to the one conventionally used by crystallographers, as defined in *International Tables for Crystallography* Volume A (*IT* A) (2005).

To generate the conventional solution, a two-step procedure is used. In step 1, the reduced primitive triclinic cell is found using the algorithm provided by *IT* A. Subsequently, step 2 finds conventional cells in the other Bravais lattices of higher symmetry.

11.4.3.1. Lattice symmetry

The relationship between a higher-symmetry cell and the reduced primitive triclinic cell can be described by

$$[\mathbf{A}] = [\mathbf{M}][\mathbf{P}], \qquad (11.4.3.5)$$

where $[\mathbf{A}]$ and $[\mathbf{P}]$ are matrices of the type $\{\mathbf{a}_0, \mathbf{b}_0, \mathbf{c}_0\}$, with $[\mathbf{P}]$ representing the reduced triclinic primitive cell, and $[\mathbf{M}]$ is one of the 44 matrices listed in *IT* A. If $[\mathbf{A}]$ is generated using equation (11.4.3.5) from an experimentally determined $[\mathbf{P}]$, owing to experimental errors it will not exactly satisfy the symmetry restraints. *DENZO* introduced a novel index to evaluate the significance of this violation of symmetry. This index is based on the observation that from $[\mathbf{A}]$ one can deduce the parameters of the unit cell, apply symmetry restraints to the unit cell and calculate a matrix $[\mathbf{A}']$ for the unit cell that satisfies these symmetry restraints. If $[\mathbf{A}]$ perfectly satisfies the symmetry restraints, the matrix $[\mathbf{U}]$, where

$$[\mathbf{U}] = [\mathbf{A}][\mathbf{A}']^{-1}, \qquad (11.4.3.6)$$

will be unitary and

$$[\mathbf{U}]^T - [\mathbf{U}]^{-1} = 0. \qquad (11.4.3.7)$$

The index of distortion calculated and presented by *DENZO* is

$$\left\{\sum_i \sum_j \left([\mathbf{U}]^T_{ij} - [\mathbf{U}]^{-1}_{ij}\right)^2\right\}^{1/2} \Big/ 6, \qquad (11.4.3.8)$$

where i and j are the indices of the 3 × 3 matrix $[\mathbf{U}]$.

---

[2] This is when the crystal oscillation angle during the measurement of a single diffraction pattern is larger than the angular reflection width.

The value of this index increases as additional symmetry restraints are imposed, starting from zero for a triclinic cell. Autoindexing in *DENZO* always finishes with a table of distortion indices for the 14 possible Bravais lattices, but does not automatically make a choice of lattice.

11.4.3.2. Lattice pseudosymmetry

The cell-reduction procedure cannot determine lattice symmetry, since it cannot distinguish true lattice symmetry from a lattice accidentally having higher symmetry within experimental error (*e.g.* a monoclinic lattice with $\beta \simeq 90^\circ$ is approximately orthorhombic). If one is not certain about the lattice symmetry, the safe choice is to assume space group $P1$, with a primitive triclinic lattice for the crystal, and to check the table again after refinement of the diffraction-geometry parameters. A reliable symmetry analysis can be done only by comparing intensities of symmetry-related reflections, which is done later in *SCALEPACK* or another scaling/merging program.

11.4.3.3. Data-collection requirements

The total oscillation range needed for autoindexing has to cover a sufficient number of spots to establish the periodicity of the diffraction pattern in three dimensions. It is also important that the oscillation range of each image is small enough so that the lunes (*i.e.* rings of spots from one reciprocal plane) are resolved. One should note that the requirement for lune separation is distinct from the requirement for spot separation. If lunes overlap, spots may have more than one index consistent with a particular position on the detector.

The autoindexing procedure described above is not dependent on prior knowledge of the crystal unit cell; however, for efficiency reasons, the search is restricted to a reasonable range of unit-cell dimensions, obtained, for example, from the requirement of spot separation. In *DENZO*, this default can be overridden by the keyword *longest vector*, but the need to use this keyword is a sign of a problem that should be fixed. Either the defined spot size should be decreased or data should be recollected with the detector further away from the crystal.

11.4.3.4. Misindexing

Autoindexing is sensitive to inaccuracy in the description of the detector geometry. The specified position of the beam on the detector should correspond to the origin of the Bragg-peaks lattice (*i.e.* the peak with Miller index 000). Autoindexing will shift the origin of the lattice to the Bragg lattice point closest to the specified beam position. An incorrect specification of the beam position will result in the incorrect placement of the Miller index 000. In such a situation, all reflections will have incorrectly determined indices. Such misindexing can be totally self-consistent until the intensities of symmetry-related reflections are compared. This dependence of the indexing correctness on the assumed beam position is one of the main sources of difficulties in indexing (Otwinowski & Minor, 1997; Gewirth, 2003). The beam position has to be precise, as the largest acceptable error is one half of the shortest distance between spots.

The process of determining $\{h, k, l\}$ triplets is not very sensitive to other detector parameters. Errors of a degree or two in rotation or by 10% in distance are unlikely to produce wrong values of h, k and l. Sometimes data with even very large errors, *e.g.* if the detector distance is too large by a factor of 5, will still produce the correct $\{h, k, l\}$ triplets. The detector position error is compensated by an error in the lattice determined by autoindexing. For this reason, the accuracy of the lattice is not a function of the autoindexing procedure, but depends mainly on the accuracy of the detector description. By the same token, the distortion of the lattice also depends on the accuracy of the detector parameters.

11.4.3.5. Twins

Special care has to be taken if more than one crystal contributes to the diffraction image. When there is a large disproportion between the volumes of the crystals (*e.g.* the presence of a satellite crystal), autoindexing may work without any modifications. In the case of crystals of similar volumes, manual removal of weaker reflections from the peak-search list and resolution cuts can make the proportion of reflections from one crystal in the peak list large enough for the autoindexing method to succeed. If the multiple crystals have similar orientations, using only very low resolution data may be the right method. In the case of twinned crystals, the autoindexing procedure sometimes finds a superlattice that simultaneously assigns integer indices to reflections from both crystals. In such a case, *DENZO* solves the problem of finding the best three-dimensional lattice that incorporates all of the observed peaks. Unfortunately, for a twinned crystal, the periodicity of the overall diffraction pattern may not in all cases be the proper criterion to index two different lattices. Alternative approaches have been described in the literature for indexing such cases.

11.4.4. Coordinate systems

There are four natural coordinate systems used to describe a diffraction experiment, defined by the order in which the diffraction-image pixels are stored in the detector, the beam and gravity, or the beam and the goniostat axis (spindle or 2θ). These coordinate systems will be called *data*, *beam–gravity*, *beam–spindle* and *beam–*2θ, respectively.

11.4.4.1. Beam–gravity

To visualize a diffraction pattern, beam–gravity is the coordinate system clearly preferred by human physiology. The universal preference to relate to the gravity direction is revealed by the observation that people generally perceive an image in a mirror as inverted left–right rather than top–down. Hence *XdisplayF* uses the beam–gravity coordinate system.[3]

11.4.4.2. Data

The first (1983) *DENZO* implementation used the data coordinate system to describe the beam position on the detector and to define the integration box. This is still the case in order to keep backward compatibility. There are eight ways of relating detector-data order to the beam–gravity coordinate system. All of them have been encountered in various detector formats and are the part of the detector-format description in *DENZO*.

11.4.4.3. Beam–spindle

Initially, *DENZO* supported only a single-axis goniostat and used a beam–spindle coordinate system to define the crystal and detector orientation, as well as polarization. The goniostat spindle axis was assumed to be horizontal, so the direction perpendicular to the beam and spindle was described by the keyword *vertical*, which in reality may not relate to the gravity direction for some goniostats. The keyword *rotx* relates to rotation around the *spindle axis*, *roty* around the *vertical axis* and *rotz* around the *beam axis*. The definition of the orientation matrix in the file used for communication between *DENZO* and *SCALEPACK* uses an unintuitive convention: the letter *y* in *roty* relates to the first element of the vector, *x* in *rotx* to the second and *z* in *rotz* to the third. However, the matrix always has a positive determinant, so this convention has no impact on the handedness of the coordinate system. This unfortunate choice of convention, preserved for backward compatibility reasons, appears only in the communication file and has no significance for anybody who does not inspect the matrix.

---

[3] There may occasionally be an exception to this when the experimental system is not known.

11.4.4.4. Beam–2θ

The description of generalized multiple-axis goniostats introduced a conceptual change in the *DENZO* coordinate system. The data-collection axis can be oriented in any direction, so in principle *rotx*, *roty* and *rotz* no longer need to be defined relative to the data-collection axis. However, to keep the useful correlations between refinable parameters (for example, *crystal rotz* and *detector rotz* are typically close to 100% correlated), one real and two virtual goniostats are used simultaneously in *DENZO*. Refinable crystal parameters (*crystal rotx*, *roty*, *rotz*) are still defined, as in the past, by the data-collection axis and the beam. This means that the directions of rotations defined by *fit crystal rotx*, *roty* and *rotz* do not rotate around the data-collection axis as the program advances from one image to another. This coordinate system changes with the change in direction of the data-collection axis. The crystal orientation is defined by three constant, perpendicular axes, which do not have to be aligned with the physical crystal goniostat. However, the so-called *2 theta* rotation has a fixed axis, and, if it exists, it defines the *DENZO* coordinate system together with the beam axis. Thus, the current coordinate system in *DENZO* should be called beam–2θ. Fortunately for the user, the conversions between different coordinate systems are handled transparently. For example, the refined change in the crystal orientation is converted from the refined axes goniostat to the crystal-orientation goniostat. The movements of the physical goniostat are converted into appropriate changes in the diffraction pattern. The physical goniostat appears only to describe the data collection and, optionally, to calculate the physical goniostat angles needed to produce particular crystal alignments.

The *DENZO* coordinate system (Gewirth, 2003) is used in the definition of crystal goniostats, 2θ goniostat and polarization. The curvature of cylindrical detectors and Weissenberg coupling are described in this coordinate system as well.

This discussion of the coordinate systems shows that the conceptual complexity of the program description can be compatible with – or even lead to – simplicity in the use of the program. The success of data analysis does not require a full understanding of the relations between internal *DENZO* goniostats and the coordinate systems when using the programs. The reason for this complexity was to create a simple pattern of correlations between crystal and detector parameters in *DENZO* refinement. This in turn allows for simple and easy-to-understand control of the refinement process and simplifies problem diagnostics. For example: the definition of refined *crystal rotx* as rotation around the data-collection axis makes the spindle and shutter problems manifest only as fluctuations of *crystal rotx*. Constant nonzero values of refined shifts between frames of *crystal roty* and *rotz* are a sign of misalignment of the data-collection axis. Although the program compensates for this misalignment with changes in crystal orientation, this introduces a small error in the Lorentz factor (which will be, to a good approximation, compensated for in scaling). The nature of these problems is such that they do not result in a complete failure of the experiment, but they do have an impact on the quality of the result. It is up to the experimenter and the instrument manager to assess the significance of these indications.

11.4.5. Experimental assumptions

To achieve the main goal of a diffraction experiment – the estimation of structure-factor amplitudes – three components need to be determined, with highest possible precision:

(1) the crystal response function, namely the relationship between the crystal structure factor and the number of diffracted X-ray photons;
(2) the detector response function; and
(3) the geometrical description of the detector relative to the directions of the X-ray beam and crystal goniostat axes.

The main difficulty of data analysis in protein crystallography is the complexity of the process that determines these components. *HKL* can determine all three directly from the data produced by the analogue-to-digital converter (ADC). The only extra program needed is one that sends the raw ADC signal to the computer disk. For charge-coupled-device (CCD) detectors, spatial detector distortion and sensitivity per pixel functions need to be established in a separate experiment. An important part of such calibration is the flood-field exposure, which can provide a pixel-by-pixel response correction for calculating the background in the X-ray exposure. There was hope that it would also correct for localized variations in response to Bragg-peak intensities, but it has been shown that light diffusion in reducing fibre optic taper depends on the stretching process during individual manufacture of such tapers. Consequently, there are substantial effects, in addition to the flood-field exposure, on Bragg-peak intensities towards the edges of such tapers. For single taper (single CCD) detectors, with the beam in the centre, the Bragg peaks are underestimated towards the edge in a resolution-dependent way, but without noticeably affecting merging statistics. The resolution-dependent effect is mostly compensated for by a slight adjustment in temperature factor of the model, so it has little practical impact. The issue is much more severe for larger, multi-taper (multi-CCD) detectors, where the localized effects may greatly affect the phasing signal. This effect can be corrected to a degree during scaling, in which geometric details of the detector construction are taken into account.

Additionally, determination of detector-geometry distortion can be accomplished with diffraction experiments on a well diffracting, high-symmetry, non-slipping crystal and a special data-collection procedure. Such a procedure can be used for experimental detectors or to correct for manufacturers' inaccuracies, which are occasionally noticeable.

In practice, many manufacturers of CCD detectors provide post-processed data rather than ADC output, to hide features and flaws of their instruments. This practice complicates data analysis, as the post-processing does not correct well for variations in CCD detector sensitivity, changes the shapes of diffraction-peak profiles and creates incorrect estimates of diffraction-peak intensities in places where flaws were hidden.

Better results would be obtained by allowing output of data directly from the ADC, letting CCD detectors approach the lower level of systematic errors observed for image-plate detectors.

11.4.5.1. Crystal diffraction

The crystal response function consists of two types of factors, which are included in the analysis: additive factors represented by the background, and a number of multiplicative factors, such as exposed crystal volume, resolution-dependent decay, Lorentz factor, flux variation, absorption, polarization *etc.* Other factors, like extinction, are currently ignored by *HKL*, except for their contribution to error estimates. Specific radiation-induced damage (Borek *et al.*, 2007, 2010) is approached differently, as it is a merging, rather than scaling-factor, correction.

11.4.5.2. Data model

The detector response function is one of the main components of the data model. The detector formats define the coordinate system, the pixel size, the detector size, the active area and the fundamental shape (cylindrical, spherical, flat rectangular or circular, single or multi-module) of the detector.

HKL supports most of the data formats representing particular combinations of the features listed below:

1. data stored in 8 or 16 bit fields;
2. overflow table;
3. linear, bilinear, polynomial and exponential response, with the error model represented by an arbitrary scale and offset;
4. saturation limit;
5. value representing lack of data;
6. constant offsets per read-out channel;
7. pattern noise;
8. lossless compression;
9. flood-field response; and
10. sensitivity response.

The main complexity of the data-analysis program and the difficulties in using it are not in the application of the data model but rather in the determination of the unknown data-model parameters. The refinement of the data-model parameters is an order of magnitude more complex in terms of the computer code than the integration of Bragg peaks when the parameters are known.

The data model is a compromise between an attempt to describe the measurement process precisely and the ability to find parameters describing this process. For example, the overlap between Bragg peaks is typically ignored due to the complexity of spot-shape determination when reflections overlap. The issue is not only to implement the parameterization, but also to do it with acceptable speed and stability of the numerical algorithms. A more complex data model can be more precise under specific circumstances, but can result in a less stable refinement and produce less precise final results in most cases. An apparently more realistic but also more complex data model may end up being inferior to a simpler and more robust approach. The complexity of model-quality analysis is due to the fact that some types of errors may be much less significant than others. In particular, an error that changes the intensities of all reflections by the same factor only changes the overall scale factor between the data and the atomic model. Truncation of the integration area results in a systematic reduction of calculated reflection intensities. A variable integration area may result in a different fraction of a reflection being omitted for different reflections. The goal of an integration method is to minimize the variation in the omitted fraction, rather than its magnitude. Similarly, if there is an error in predicting reflection-profile shape, a constant error has a smaller impact than a variable error of the same magnitude.

The magnitudes and types of errors are very different in different experiments. The compensation of errors also differs between experiments, making it hard to generalize about an optimal approach to data analysis when the data do not fully satisfy the assumptions of the data model. For intense reflections, when counting statistics are not a limiting factor, none of the current data models accounts for all reproducible errors in experiments. This issue is critical in measuring small differences originating from dispersive effects, *i.e.* anomalous scattering.

11.4.5.3. Data-model refinement

The parameters of the data model can be classified into four groups:

1. Those determined and refined from self-consistency of the data by a (nonlinear) least-squares method.
2. Parameters that can be determined from internal self-consistency of the data, but for which least squares are not implemented.
3. Parameters that have to be established in a separate experiment, *e.g.* pixel sensitivity from flood-field exposure.
4. Parameters that are obtained from a description of the hardware.

The least-squares method is based on minimization of a function that is a sum of contributors of the following type:

$$(\mathrm{pred} - \mathrm{obs})^2/\sigma^2 = \chi^2, \qquad (11.4.5.1)$$

where pred is a prediction based on some parameterized model, obs is the value of this prediction's measurement and σ^2 is a combined estimate of the measurement and the prediction uncertainties (variance). *DENZO* refines the following parameters by least-squares methods:

1. unit-cell vectors in autoindexing;
2. reflection background and background slope; and
3. crystal orientation, unit cell, mosaicity, beam focus and position, detector orientation and position, and geometrical distortions that are parameterized differently for different types of detectors.

SCALEPACK can refine the following parameters by least-squares methods:

1. unit cell, crystal orientation and mosaicity, including changes of these parameters during an experiment;
2. goniostat internal alignment angles;
3. crystal absorption, using a spherical-harmonic expansion (Katayama, 1986; Blessing, 1995) of the absorption surface;
4. uniformity of exposure, including shutter-timing error;
5. correction to the Lorentz factor, resulting from misalignment of the spindle axis;
6. reproducible wobble of the rotation axis, resulting from misalignment of gears in a spindle assembly;
7. non-uniform smooth detector response, resulting (for example) from light diffusion in the fibre optic taper not correctable by flood-field exposure; and
8. other factors contributing to scaling, such as slow fluctuations of beam intensity, changes in exposed volume of the crystal, overall crystal decay and resolution-dependent crystal decay.

SCALEPACK can also refine, by Tikhonov-stabilized least-squares methods (Borek *et al.*, 2010), multiple structure-factor components contributing to a group of reflections with the same unique index:

(1) the zero-dose extrapolated intensity of a unique reflection;
(2) perturbations resulting from Friedel-symmetry violations (the so-called anomalous signal);
(3) perturbations resulting from wavelength-dependent changes (the so-called dispersive f' differences);
(4) perturbations resulting from radiation-induced specific changes of structure factors;
(5) other changes in structure, resulting from differences between crystals or pseudosymmetry (imperfect rotational symmetry);
(6) higher-order terms of all the above-mentioned effects.

11.4.5.4. Correlation between parameters

Occasionally, the refinement can be unstable due to high correlation between some parameters. Refinement of highly correlated parameters, for example positional refinement of unit-cell parameters and the distance between the crystal and the detector, results in the errors in one parameter compensating for errors in other parameters. However, such error compensation may still lead to mostly correct predictions; for example, incorrect distance and unit-cell parameters can result in correct predictions of the diffraction pattern. In an extreme case, where compensation is 100%, the parameters involved would be undefined, but the error compensation by other parameters involved would be undefined even when the diffraction-pattern prediction is successful.

To prevent instability in calculations, eigenvalue filtering (Reeke, 1984) is employed to remove the most correlated components from the refinement. Eigenvalue filtering works reliably when the starting parameters are close to the correct values. It may fail, however, to correct large errors in the input parameters if the correlation between parameters is close to 100%. All refinements have also built-in Tikhonov or Tikhonov-like stabilizers (Tikhonov & Arsenin, 1977) to prevent unreasonable values of parameters or differences between them.

Once the whole data set is integrated, post refinement (Rossmann, 1979; Winkler *et al.*, 1979; Evans, 1987; Greenhough, 1987; Kabsch, 1993) can refine unit-cell parameters and crystal-orientation parameters more precisely and without correlation with detector parameters. For this reason, the unit-cell parameters used in structure-determination calculations should come from the post refinement performed in *SCALEPACK* and not from initial refinement in *DENZO*.

11.4.5.5. Single- and multiframe refinement

The crystal and detector orientation parameters can be refined either for a group of images or for each processed image separately. Refinement performed separately for each image allows for robust data processing, even when the crystal slips considerably during data collection.

11.4.5.6. Active area

Not every pixel represents a valid measurement. Specification of the active detector area in *DENZO* is derived from the format and the definition of the detector size. Detector calibration with flood-field exposure will calculate the sensitivity for each pixel and will also determine which pixels should be ignored. Unfortunately, rather than ignoring bad areas, some manufacturers enter values interpolated from nearby pixels, in particular to present a fake contiguous image for multi-module detectors. This practice results in observations in these areas not scaling well with their symmetry equivalents.

The input command in *DENZO* can additionally label some areas of the detector to be ignored, most frequently the shadow caused by the beam stop and its support. There are also commands to ignore triangular shapes, margins of the detector and a particular line or pixel.

11.4.5.7. Flood field

The basic method for calibration of the spatial dependence of detector sensitivity is to measure the response of the detector to a flood-field exposure. The amount of relative exposure per pixel needs to be known. *DENZO* allows for either a uniform or an isotropic source. If the source is at the crystal position, *DENZO* refinement (with a separate crystal exposure) can be used to define the geometry of the source relative to the detector. To calculate the flood-field response, a prior determination of the detector distortion is required. The flood-field response is converted to a sensitivity function. Large deviations from the local average are used to define inactive pixels. The edge of the active area needs special treatment, dependent on the method of phosphorus deposition.

11.4.5.8. Absolute configuration

Absolute configuration is defined relative to the data-coordinate system and is only affected by the sign of the parameter *y scale*. A combined mirror transformation of the image data and of the goniostat description does not affect the self-consistency of the data. Thus, the correctness of the absolute configuration cannot be verified by data-reduction programs. Owing to inherent ambiguities in indexing when merging data from different crystals, re-indexing is sometimes necessary, which may cause unjustified concern that the re-indexing may somehow affect the sign of Bijvoet differences. *SCALEPACK* checks for the positive sign of the re-indexing matrix, and thus the procedure cannot affect the absolute configuration or the Bijvoet differences.

11.4.5.9. Detector goniostat

The detector goniostat in *DENZO* can have only one rotation axis – 2θ. In the complex transformations described in equation (11.4.2.8), the geometrical scale is affected by pixel-to-millimetre conversion and distortion. For different instruments, the scale of the rotation is defined differently. For detectors without distortion, the scale is defined by the value of the pixel size in the 'slow' direction. For detectors with distortion characterized by polynomials (*e.g.* CCD detectors), the scale is defined in the way the distortion was determined. In such a case, the scale is derived either from the separation between holes in the reference grid mask or the detector translation. As the distance of the detector active surface from the crystal cannot be measured precisely, in the latter approach the difference between the two distances is the ultimate source of the scale reference. The angle between the detector distance translation and the X-ray beam completes the definition of the detector goniostat in *HKL*.

11.4.5.10. Crystal goniostat

Each type of physical goniostat is defined by six angles. Two angles define the direction of the main axis (ω) in the *DENZO* coordinate system. The third angle defines the zero position of the ω axis. The fourth is the angle between ω and the second axis (κ or χ). The fifth defines the zero position of the second axis. The sixth is the angle between the second and the third axes. This type of goniostat definition allows for the specification of any three-axis goniostat (EEC Cooperative Workshop on Position-Sensitive Detector Software, 1986). Misalignment of the goniostat is represented as an adjustment to these angles, which can be refined by the *HKL* system.

11.4.5.11. Crystal orthogonalization convention

Crystal orientation specified by the three angles needs a definition of a zero point. Any crystal axis, or the equivalent reciprocal-space zone perpendicular to it, can be used as a reference. The definition of zero point aligns the crystal axis with the beam direction and one of the reciprocal axes with the x direction in the *DENZO* coordinate system. The user can specify which crystal axes will be aligned at zero crystal orientation angles by specifying the so-called reference zone.

11.4.5.12. Refinement and calibration

Both the refinement and calibration procedures determine the properties of the instrument. The principal difference between refinement and calibration is that calibration is performed with data not obtained during the current diffraction experiment, and refinement uses data obtained during the current diffraction experiment. *DENZO* performs both refinement and calibration. In some cases, the difference between calibration and refinement is a question of semantics, as the refined data from one experiment can be used as a reference for another experiment, or even as a reference for a subsequent refinement cycle or for another part of the same experiment.

11.4.6. Prediction of the diffraction pattern

The autoindexing procedure assigns Miller indices only to strong spots, ones that can be found through a peak-search procedure. The target of the experiment is to estimate structure-factor amplitudes for all reflections captured by the detector. Therefore, positions of all spots need to be predicted by applying the following equations to all possible triplets $\mathbf{h}$. Using

$$\mathbf{S} = [\mathbf{A}]^{-1}\mathbf{h}, \qquad (11.4.6.1)$$

a matrix $[\mathbf{A}]$ must be found that generates the vector $\mathbf{S}$ that satisfies the diffraction condition [equation (11.4.2.1)], knowing that the matrix $[\mathbf{A}]$ is a function of the crystal orientation at the goniostat angles that generated the reflection with indices $\mathbf{h}$ [equation (11.4.2.6)]. The rotation of the crystal during the experiment creates a straightforward algebraic problem that results in a complex equation defining the angle at which the reflection occurs. This angle consequently defines the image or images on which the reflection appears. Knowing this angle, the vector $\mathbf{S}$ can be calculated, and, from equation (11.4.2.5), the direction of the vector $\mathbf{X}$ can be found:

$$\mathbf{X}/|\mathbf{X}| = \lambda(\mathbf{S} - \mathbf{S}_0). \qquad (11.4.6.2)$$

Calculation of the length of vector $\mathbf{X}$ requires a knowledge of detector orientation, which, for flat detectors, is described here by vector $\mathbf{G}$, perpendicular to the detector and with length equal to the crystal-to-detector distance:

$$\mathbf{Y} = [\mathbf{R}_{2\theta}]^{-1}\lambda(\mathbf{S} - \mathbf{S}_0), \qquad (11.4.6.3)$$

$$\mathbf{H} = [\mathbf{R}_z]^{-1}[\mathbf{R}_y]^{-1}[\mathbf{R}_x]^{-1}\mathbf{G}, \qquad (11.4.6.4)$$

$$\mathbf{X} = [\mathbf{R}_{2\theta}]\frac{\mathbf{H}\cdot\mathbf{H}}{\mathbf{Y}\cdot\mathbf{H}}\mathbf{Y}. \qquad (11.4.6.5)$$

Then, by inverting equation (11.4.2.8), the position in pixels $\{p, q\}$ of the reflection can be calculated:

$$\begin{aligned}\{p, q\} = {} & [\mathbf{D}]^{-1}[\mathbf{K}]^{-1}([\mathbf{L}]^{-1}([\mathbf{R}_{2\theta}]^{-1}([\mathbf{R}_z]^{-1}[\mathbf{R}_y]^{-1}[\mathbf{R}_x]^{-1}(\mathbf{X} - \mathbf{T}_D) \\ & + \mathbf{T}_D) - \mathbf{T}_D) + \mathbf{B}).\end{aligned} \qquad (11.4.6.6)$$

11.4.6.1. Refinement of crystal and detector parameters

The precision of the integration step depends on precise knowledge of the peak positions. The autoindexing step provides only an approximate orientation of the crystal, and the result of that step is imprecise if the initial values of the detector parameters are poorly known. A nonlinear least-squares refinement process is used to improve the prediction (EEC Cooperative Workshop on Position-Sensitive Detector Software, 1986). Depending on the particulars of the experiment, the same parameters (*e.g.* crystal-to-detector distance) may either be known more precisely *a priori*, or are better estimated from the diffraction data. *DENZO* allows either fixing or refining of each of the parameters separately. This flexibility is important when characterizing a detector, but when detector parameters are already known, the *fit all* option and detector-specific default values are quite reliable.

DENZO can refine the six parameters describing the position and orientation of the detector in space. It can also refine internal parameters of the detector including:

(1) curvature radius and rotation of the active surface – *film rotation*, for cylindrical detectors;
(2) x to y scale and x to y skew;
(3) radial/angular distortion for spiral scanners; and
(4) polynomial distortion, separate for each CCD module of multi-CCD detectors (Naday *et al.*, 1998).

Detector- and crystal-parameter refinement in *DENZO* is achieved by minimizing the sum of three functions [equations (11.4.6.7), (11.4.6.8) and (11.4.6.11)] of the type in equation (11.4.5.1). The contribution resulting from the measurement of position $\{p, q\}$ of the reflection is

$$\chi_p^2 = \sum_{hkl}(p_{\rm pred} - p_{\rm cent})^2/\sigma_p^2, \qquad (11.4.6.7)$$

$$\chi_q^2 = \sum_{hkl}(q_{\rm pred} - q_{\rm cent})^2/\sigma_q^2. \qquad (11.4.6.8)$$

where $p_{\rm pred}, q_{\rm pred}$ is the predicted position of the reflection in pixel coordinates, $p_{\rm cent}, q_{\rm cent}$ is the centroid position of the observed reflection in pixel coordinates and σ_p, σ_q are combined estimates of uncertainties of the observed and predicted positions.

11.4.6.2. Bragg's law for non-ideal conditions: mosaicity

The Bragg condition [equation (11.4.2.1)] assumes diffraction from ideal crystals and a parallel X-ray beam. In reality, crystals are mosaic and the beam has some angular spread. The value of the *mosaicity* keyword describes the range of orientations of the crystal lattice within a sample. As the impacts of mosaicity and the beam's angular spread on the angular width of reflections are equivalent, the keyword *mosaicity* describes the sum of both effects.

DENZO assumes the following model of angular shape of diffraction peaks for the oscillation angle φ:

$$M = \frac{\text{mos}}{\pi}\left[1 + \cos\frac{\pi(\varphi - \varphi_c)}{\text{mos}}\right], \qquad (11.4.6.9)$$

where mos is the observed angular width of a diffraction peak yet to be increased by the Lorentz factor, φ_c is the predicted oscillation angle at which the diffraction condition is fulfilled, φ is in the range($\varphi_c - \text{mos}/2$; $\varphi_c + \text{mos}/2$), otherwise $M = 0$. The actual width of the reflection is different due to Lorentz-factor variability over the image, so equation (11.4.6.9) describes only the common component of the angular width.

Using equation (11.4.6.9) we can calculate

$$P_{\varphi_1\varphi_2} = \int\limits_{\varphi_1}^{\varphi_2} M(\varphi)\,\mathrm{d}\varphi. \qquad (11.4.6.10)$$

P is the predicted partiality of data collected by oscillating from φ_1 to φ_2. It is a number that represents what fraction of the reflection intensity is present in one image. If the partiality is 1, such reflections are called fully recorded; otherwise, they are called partials. For partials, predictions of partiality can be compared with the observed fraction P_0 of the reflection intensity present in one image. The partiality model contributes the following term to the refinement:

$$\chi^2_P = (P_{\varphi_1\varphi_2} - P_0)^2/\sigma^2_{P_0}. \qquad (11.4.6.11)$$

The combined positional [described by equations (11.4.6.7) and (11.4.6.8)] and partiality refinement [equation (11.4.6.11)] used in *DENZO* is both stable and very accurate. The power of this method lies in proper weighting by estimated errors of two very different terms – one describing positional differences and the other describing intensity differences. Both detector and crystal variables are uniformly treated in the refinement process.

11.4.6.3. Detector distortions

The design of detectors results in pixels not being positioned on an exact square or rectangular grid. A correct understanding of the detector distortions is essential to accurate positional refinement. The types of distortions are detector-specific. The primary sources of error include misalignment of the detector position sensors and optical or magnetic distortion in CCD-based detectors. If the detector distortion can be parameterized, then these parameters should be added to the refinement. For example, in the case of spiral scanners, there are two parameters describing the end position of the scanning head. In a perfectly adjusted scanner, these parameters would be zero. In practice, however, they may deviate from zero by as much as 1 mm. Such misalignment parameters can correlate very strongly with other detector and crystal parameters, particularly for low-symmetry lattices or for low-resolution data. If the distortions are stable, it is better to determine them in a separate experiment optimized for that task.

Fibre-optic tapers used in many CCD detectors have distortions that have to be individually determined for each instrument. The distortion is stable over time and its spatial characteristics are dominated by a smooth component and a small local shear. In high-quality tapers used in X-ray instruments, the small local shear can be ignored. The smooth component can be parameterized in a number of ways, for example by splines or polynomials (Messerschmidt & Pflugrath, 1987). *DENZO* uses two-dimensional Chebyschev polynomials (Press *et al.*, 1989) in $\{x, y\}$ or $\{p, q\}$ coordinates, normalized to the range $\{[-1, +1], [-1, +1]\}$. Typically, fifth- or seventh-order polynomials result in a positional error (r.m.s.) lower than 7 µm, which is about one tenth of a typical detector pixel. *DENZO* can use either a grid mask pattern or the X-ray diffraction pattern to refine the coefficients of the Chebyschev polynomials. If a grid mask is used, it has to be precisely made and positioned. The use of crystallographic data requires precise knowledge of detector and crystal parameters that are not known *a priori* with the required precision. The crystal and detector parameters can be determined in the same experiment as detector distortion. However, this experiment needs to be designed to minimize the impact of correlations between the parameters involved. The data analysis requires the description of the distortion function and its inverse. In *DENZO*, both are approximated in terms of Chebyschev polynomials. The magnitude of the approximation error is the same for the distortion function and its inverse.

11.4.7. Integration of diffraction maxima by profile fitting

To accurately integrate diffraction peaks, the spot position has to be predicted accurately. Each integration program has its own procedure for predicting and fitting diffraction profiles. In *DENZO*, profile-shape prediction is defined by a weighted average of other reflection profiles present within some radius from the spot of interest. Each spot has its own prediction, which is continuously adjusted to variations of spot shapes over the detector. The profiles are added by shifting them to the same position, generating a normalized profile P_i, where $\sum_i P_i = 1$. In the second step, the measured pixels' values are fitted to a function

$$B_i + IP_i, \qquad (11.4.7.1)$$

where B_i is the predicted value for the background in pixel i and I is the diffraction intensity of the spot. The profile-fitting procedure minimizes the function

$$\sum_i \frac{[M_i - (B_i + IP_i)]^2}{V_i}, \qquad (11.4.7.2)$$

where M_i are the measured pixel values and V_i are the variances of these measurements. The minimum of this function defines the value of the profile-fitted intensity (Otwinowski & Minor, 1997):

$$I = \frac{\sum_i P_i(M_i - B_i)/V_i}{\sum_i P_i^2/V_i}. \qquad (11.4.7.3)$$

11.4.8. Scaling – multiplicative corrections

The relation between the measured intensity $I(hkl)$ of reflection hkl and its squared structure-factor amplitude $|\mathbf{F}(hkl)|^2$ is described by

$$I(hkl) = I_b r_e^2 \frac{\lambda^2}{|\mathbf{S} \times \boldsymbol{\omega}'|} PT \frac{V}{v_u^2} |\mathbf{F}(hkl)|^2 D_A D_S, \qquad (11.4.8.1)$$

where I_b is the flux density of the primary beam; $r_e = e^2/m_e c^2$ is the classical electron radius (2.818×10^{-12} mm); λ is the wavelength of the beam; $\mathbf{S} \times \boldsymbol{\omega}'$ is a cross product between the diffraction vector $\mathbf{S}$ and $\boldsymbol{\omega}'$ (the projection of the crystal-rotation-speed vector $\boldsymbol{\omega}$ on the plane perpendicular to the primary beam;

thus $|\boldsymbol{\omega}|/|\mathbf{S}\times\boldsymbol{\omega}'|$ is the Lorentz factor); P is a polarization factor (Azaroff, 1955); T is the transmission of the beam [related to the absorbance defined as $A = -\ln T$, $T = \exp(-A)$]; v_u is the volume of a primitive crystal unit cell; V is the volume of the crystal exposed to the beam; $|\mathbf{F}(hkl)|^2$ is the square of the structure-factor amplitude for the given reflection hkl; D_A is the absorption of X-rays by the detector's active material; and D_C is the detector's response to a single absorbed X-ray photon.

SCALEPACK determines the components of the total scale factor, *i.e.* the product of all factors that multiply the structure-factor amplitudes squared in equation (11.4.8.1):

$$I(hkl) = K|\mathbf{F}(hkl)|^2, \qquad (11.4.8.2)$$

where I is the intensity and K is the total scale factor.

All components of the total scale factor K can be calculated from non-diffraction measurements and calibration of the data-collection system. However, the absolute calibration of the whole system is rarely available and part of the scale factor (the overall scale factor k_o) is determined by comparing the scaled data to the squared structure-factor amplitudes predicted from an atomic model obtained after the structure is solved:

$$K = k_o k_r = k_o(k_{\rm beam}\, k_{\rm polarization}\, k_{\rm detector}\ldots). \qquad (11.4.8.3)$$

The relative scale factor k_r is calculated, but in practice we assume that some of its components are known from detector calibration, beam monitoring and the diffraction geometry. The scaling procedure determines the remaining parts of the scale factor (often iteratively), based on knowledge from subsequent stages of crystallographic analysis. When iterative procedures are applied, the scaling model has to include information about experimental uncertainties (discussed in Section 11.4.10).

SCALEPACK uses an exponential modelling approach (Otwinowski *et al.*, 2003), which is flexible with regard to correlations among parameters and provides a uniform description of the parameter optimization process for various scaling models. In *SCALEPACK* scale factors s_i for each observation are calculated using a set of *a priori* unknown parameters p_i:

$$s_i = \exp\left[\sum_i p_i\, f_i(hkl)\right], \qquad (11.4.8.4)$$

where f_i are pre-defined modelling functions of experimental conditions and i is a hierarchical index referring both to the type of correction and to the indices of the functional parameters describing this correction.

The simplest scaling model has a separate scale factor for each group (or batch) of data, *e.g.* one scale factor per image. In such a case,

$$f_{i_s} = \delta_{ij}, \qquad (11.4.8.5)$$

where j is the batch index for a particular reflection. From equation (11.4.8.4) we obtain P_{i_s} as the logarithm of the scale factor of batch i.

To correct for a radiation-damage component represented as resolution-dependent decay, one temperature factor is used per batch of data,

$$f_{i_B} = [(\mathbf{S}\cdot\mathbf{S})/2]\delta_{ij}, \qquad (11.4.8.6)$$

where $\mathbf{S}$ is the scattering vector for each reflection. Using the same approach as for equation (11.4.8.5), p_{i_B} is obtained as the relative temperature factor.

Another, more complex, multiplicative correction addresses unknown crystal absorption using an average of absorbances in the incoming and diffracted beam directions (Kopfmann & Huber, 1968). The correction is parameterized by real spherical harmonics as a function of the direction of the incoming beam and the diffraction vector $\mathbf{S}$, expressed in the polar coordinate system of the rotating crystal (Katayama, 1986; Blessing, 1995):

$$\begin{aligned} f_{as,lm} &= \frac{1}{2}\left[\frac{(2l+1)(l-m)!}{4\pi(l+m)!}\right]^{1/2}[P_{lm}(\cos\theta_i)\sin(2\pi m\Phi_i) \\ &\quad + P_{lm}(\cos\theta_o)\sin(2\pi m\Phi_o)], \\ f_{ac,lm} &= \frac{1}{2}\left[\frac{(2l+1)(l-m)!}{4\pi(l+m)!}\right]^{1/2}[P_{lm}(\cos\theta_i)\cos(2\pi m\Phi_i) \\ &\quad + P_{lm}(\cos\theta_o)\cos(2\pi m\Phi_o)], \end{aligned} \qquad (11.4.8.7)$$

where as, lm and ac, lm are parts of the hierarchical index i from equation (11.4.8.4); l, m are indices of the spherical harmonics; P_{lm} is a Legendre polynomial; and θ, Φ are the polar coordinates of the incoming (index i) and the outgoing (index o) directions in the crystal coordinate system. The odd-order spherical harmonics should have zero coefficients when describing pure absorption of X-rays. However, due to correlation with other effects, the scaling may benefit from the inclusion of low-order odd-order harmonics.

It is beneficial to correct even for a small discrepancy between the actual and assumed directions of the crystal rotation axis. The inaccuracy results in an error in the calculated value of the Lorentz factor [equation (11.4.8.1)]. The scale factor to correct for this error can be described using the parameter p_l, the value of which represents a small angular error. The corresponding function is

$$f_l = \frac{\mathbf{S}\cdot\boldsymbol{\omega}'}{|\mathbf{S}\times\boldsymbol{\omega}'|}. \qquad (11.4.8.8)$$

There are additional effects that are parameterized using exponential modelling [equation (11.4.8.4)], for example, a correction for uneven crystal rotation and/or exposure (Otwinowski *et al.*, 2003), or a correction for uneven detector response, which is very important for multi-CCD detectors. This approach can be extended to other experimental factors if there is a need to correct them during scaling without changing the overall logic of scale-factor determination (Otwinowski *et al.*, 2003).

11.4.8.1. Global and local scaling

In principle, global scaling can be followed by local scaling (Matthews & Czerwinski, 1975). Local scaling is mostly applied to calculate differences of phasing signal, where it is assumed that a group of measurements, *e.g.* those close together in reciprocal space or detector space, should be on a similar scale. A flexible parameterization by the exponential modelling allows for a good description of all kinds of smooth corrections. Local scaling is much more limited in terms of what type of smooth variation is being corrected for, so it is unlikely to provide additional benefit to the general scaling method described here. In practice, if there is an improvement from such procedures at the stage of heavy-atom search, it implies that the scaling parameters for global scaling were not properly chosen.

11.4.8.2. Stabilization of scaling parameters based on prior knowledge

The unknown parameters in equation (11.4.8.4) are estimated with various level of uncertainty depending on the multiplicity of observations and how symmetry-equivalent reflections are related to each other. Potentially, this may result in unreasonable values of scaling parameters due to insufficient information to determine the values of parameters. In *SCALEPACK*, the method to stabilize such ill-conditioned calculations is closely related to Tikhonov stabilization (Tikhonov & Arsenin, 1977), where additional, *a priori* knowledge about the expected magnitude of the physical effect modelled is used to restrain the solutions, based on the same argument as in the case of restraints in the atomic refinement.

For example, logarithms of scale factors typically do not fluctuate by more than w_s between frames, where expectation about w_s is a function of the data-collection stability (beam stability, goniostat and/or crystal vibrations). This knowledge is described by adding a penalty term (*scale restrain*) to the functions being optimized:

$$(1/w_s^2)(p_{i_s} - p_{(i+1)_s})^2. \tag{11.4.8.9}$$

A similar approach can be used in calculations of absorption coefficients. For smooth absorption with the expectation of decreasing magnitude of parameters for high orders of spherical harmonics [equation (11.4.8.7)], a reasonable restraint term parameterized by w_a results in

$$\frac{l^2(p^2_{as,lm} + p^2_{ac,lm})}{w_a^2}. \tag{11.4.8.10}$$

If we do not want to penalize high-order terms more than the low-order ones, the following restraint can be used:

$$\frac{(p^2_{as,lm} + p^2_{ac,lm})}{w_a^2}. \tag{11.4.8.11}$$

11.4.9. Global refinement or post refinement

The process of refining crystal parameters using the combined reflection intensity measurements is known as global refinement or post refinement (Rossmann, 1979; Evans, 1993). The implementation of this method in *SCALEPACK* allows for separate refinement of the orientation of each image, but with the same unit-cell value for the whole data set. In each batch of data (a batch is typically one image), different unit-cell parameters may be poorly determined. However, in a typical data set there are enough orientations to determine all unit-cell lengths and angles precisely. Global refinement is also more precise than the processing of a single image in the determination of crystal mosaicity and the orientation of each image.

11.4.10. Merging – assessment of the error model and signal magnitudes in the data

Proper error estimation requires the use of Bayesian reasoning and a multi-component error model (Schwarzenbach *et al.*, 1989; Evans, 1993). In principle, the error estimates may be derived solely from a theoretical understanding of the measurement process. However, the complexity of error propagation and correlations between various sources of effects have led crystallographers to rely on hybrid approaches also involving self-consistency analysis of symmetry-equivalent reflections.

11.4.10.1. Estimation of random errors

The random errors in *DENZO* are estimated by a heuristic procedure that also accounts for small components of systematic errors (Borek *et al.*, 2003). Initially, *DENZO* estimated errors of integrated diffraction peaks from X-ray film. After introducing detectors with larger dynamic range, the procedure was adjusted accordingly.

The initial estimates of errors are obtained by

$$\sigma_0 = \frac{1}{\sum_i P_i^2/(B_i + P_i I)} \times \left\{ e_d \left[\sum_i P_i^2 (B_i + P_i I) + \frac{e_d}{n_b} \sum_i \frac{P_i^2 B_i}{(B_i + P_i I)^2} \right] \right\}^{1/2}, \tag{11.4.10.1}$$

where n_b is the number of pixels used in background estimation and e_d is the error-density parameter defined for each instrument, which can also be overridden by the user (Gewirth, 2003) with other variables defined in equation (11.4.7.1). The sums are calculated over all the pixels in a reflection profile. The expression within the braces { } describes two components of uncertainty: the left sum accounts for contributions resulting from pixels in the peak area, whereas the right sum adds an adjustment resulting from uncertainty of the background estimate. The denominator in the front of the expression in braces is derived from error propagation for the profile-fitted intensity [equation (11.4.7.3)].

Next, the goodness-of-profile-fitting factor g is calculated:

$$g = \left[\frac{1}{(n_i - 1)} \sum_i \frac{(M_i - B_i - P_i I)^2}{e_d (B_i + P_i I)} \right]^{1/2}, \tag{11.4.10.2}$$

where n_i is the number of pixels in a reflection profile. For weak reflections the parameter g should be relatively close to 1. If it is systematically off by a large factor, the error-density parameter e_d should be adjusted (Borek *et al.*, 2003). *SCALEPACK* applies an additional level of adjustment to the estimates produced by *DENZO* (Borek *et al.*, 2003):

$$\sigma_S = 1.2 \sigma_o g^{1/2}, \tag{11.4.10.3}$$

which is scaled either by the user or by an automatically adjustable factor E_S (called the error scale factor) to make disagreements among symmetry-related measurements consistent:

$$\sigma_I = E_S \sigma_S. \tag{11.4.10.4}$$

Even this scaled estimate of random error σ_I does not account for all types of errors and additional adjustments for systematic effects are needed.

11.4.10.2. Estimation of multiplicative errors

The multiplicative scale factor has its own uncertainty independent of random errors with typical values in the range of a few per cent. However, even such small errors are important in calculations of the phase signal. Errors in the scale factors have a correlated component that equally affects measurements of intensities in phasing differences, so it does not impact on the differences themselves. The important part is estimating the magnitude of the remaining component of scaling errors, described by σ_K. Comparing symmetry-related reflections estimates only the relevant component of multiplicative errors. The total scaling error would have to be estimated differently, but typically it has little relevance to macromolecular crystallography and can be ignored.

The σ_I [equation (11.4.10.4)] can be combined with σ_K to obtain the final estimated error of the scaled measurement:

$$\sigma_E = (1/K)(\sigma_I^2 + I^2 \sigma_K^2)^{1/2}. \tag{11.4.10.5}$$

11.4.10.3. Merging and signal validation

Symmetry-related scaled measurements $I(hkl)$ and their uncertainty estimates σ_E are used to obtain merged intensities by a standard weighted averaging formula:

$$\langle I \rangle = \frac{\sum_j I_j/\sigma_{E,j}^2}{\sum_j 1/\sigma_{E,j}^2}. \qquad (11.4.10.6)$$

This allows for calculations of validation statistics, called goodness-of-fit or normalized χ^2, for each unique index:

$$\chi^2 = \left(\frac{1}{n-1}\right)^{1/2} \sum_j \frac{(I_j - \langle I \rangle)^2}{\sigma_{E,j}^2}, \qquad (11.4.10.7)$$

where n represents the number of observations of a given unique index. This χ^2 statistic is then averaged in resolution shells or over intensity bins or batch number. If the error model accounts properly for all effects, the χ^2 statistic should fluctuate around a value of unity. If χ^2 values depart from this expectation it may indicate a number of possibilities, *e.g.* various problems at earlier stages (poorly edited beam-stop shadow, hardware failures, mistakes in processing or other source of outliers *etc.*), inadequacy of the error model or variations in the structure factors within the symmetry-related observations. The instrumental problems or mistakes in processing should be corrected. The effects that cannot be corrected may be handled by adjusting the error model. However, if the more detailed analysis eliminates the obvious source for such problems, then the most likely source of discrepancies between symmetry-related measurements results from violation of Friedel symmetry. *SCALEPACK* calculates merging statistics both for the Bijvoet pairs merged together and separately. Differences in χ^2 values between these two merging outputs are very reliable estimates of anomalous signal strength. When a more detailed analysis eliminates the obvious reasons for high χ^2 values, the most likely remaining source of error is non-isomorphism (Borek *et al.*, 2007, 2010).

11.4.11. Detector diagnostics

The *HKL* package has a number of tools that can detect possible detector or experimental setup problems (Otwinowski & Minor, 1997; Otwinowski *et al.*, 2003). Visual inspection of the image may provide only a very rough estimate of data quality. A check of the analogue-to-digital converter can provide rough diagnostics of detector electronics. Examination of the background can provide information about detector noise, especially when uncorrected images can be examined in the areas exposed to X-rays and areas where pure read-out noise can be observed. *DENZO* provides several diagnostic tools during the integration stage, as the crystallographer may observe crystal slippage, a change of unit-cell parameters or a change of the values of positional and angular χ^2 during the refinement.

Even more tools are provided at the data-scaling stage. By observing scale factors, poor crystal alignment can be detected. Other tools may help diagnose X-ray shutter malfunction, spindle-axis alignment and internal detector-alignment problems. The final inspection of outliers may again provide valuable information about detector quality. The clustering of outliers in one area of the detector may indicate a damaged surface; if most outliers are partials, it may indicate a problem with spindle backlash or shutter control. The zoom mode may be used to display the area around the outliers to identify the source of a problem: for example, the existence of a satellite crystal or single pixel spikes due to electronic failure. Sometimes, even for very strong data, a histogram of the pixel intensities may stop below the maximum valid pixel value, indicating saturation of the data-acquisition hardware or software.

11.4.12. *HKL-2000* and *HKL-3000*

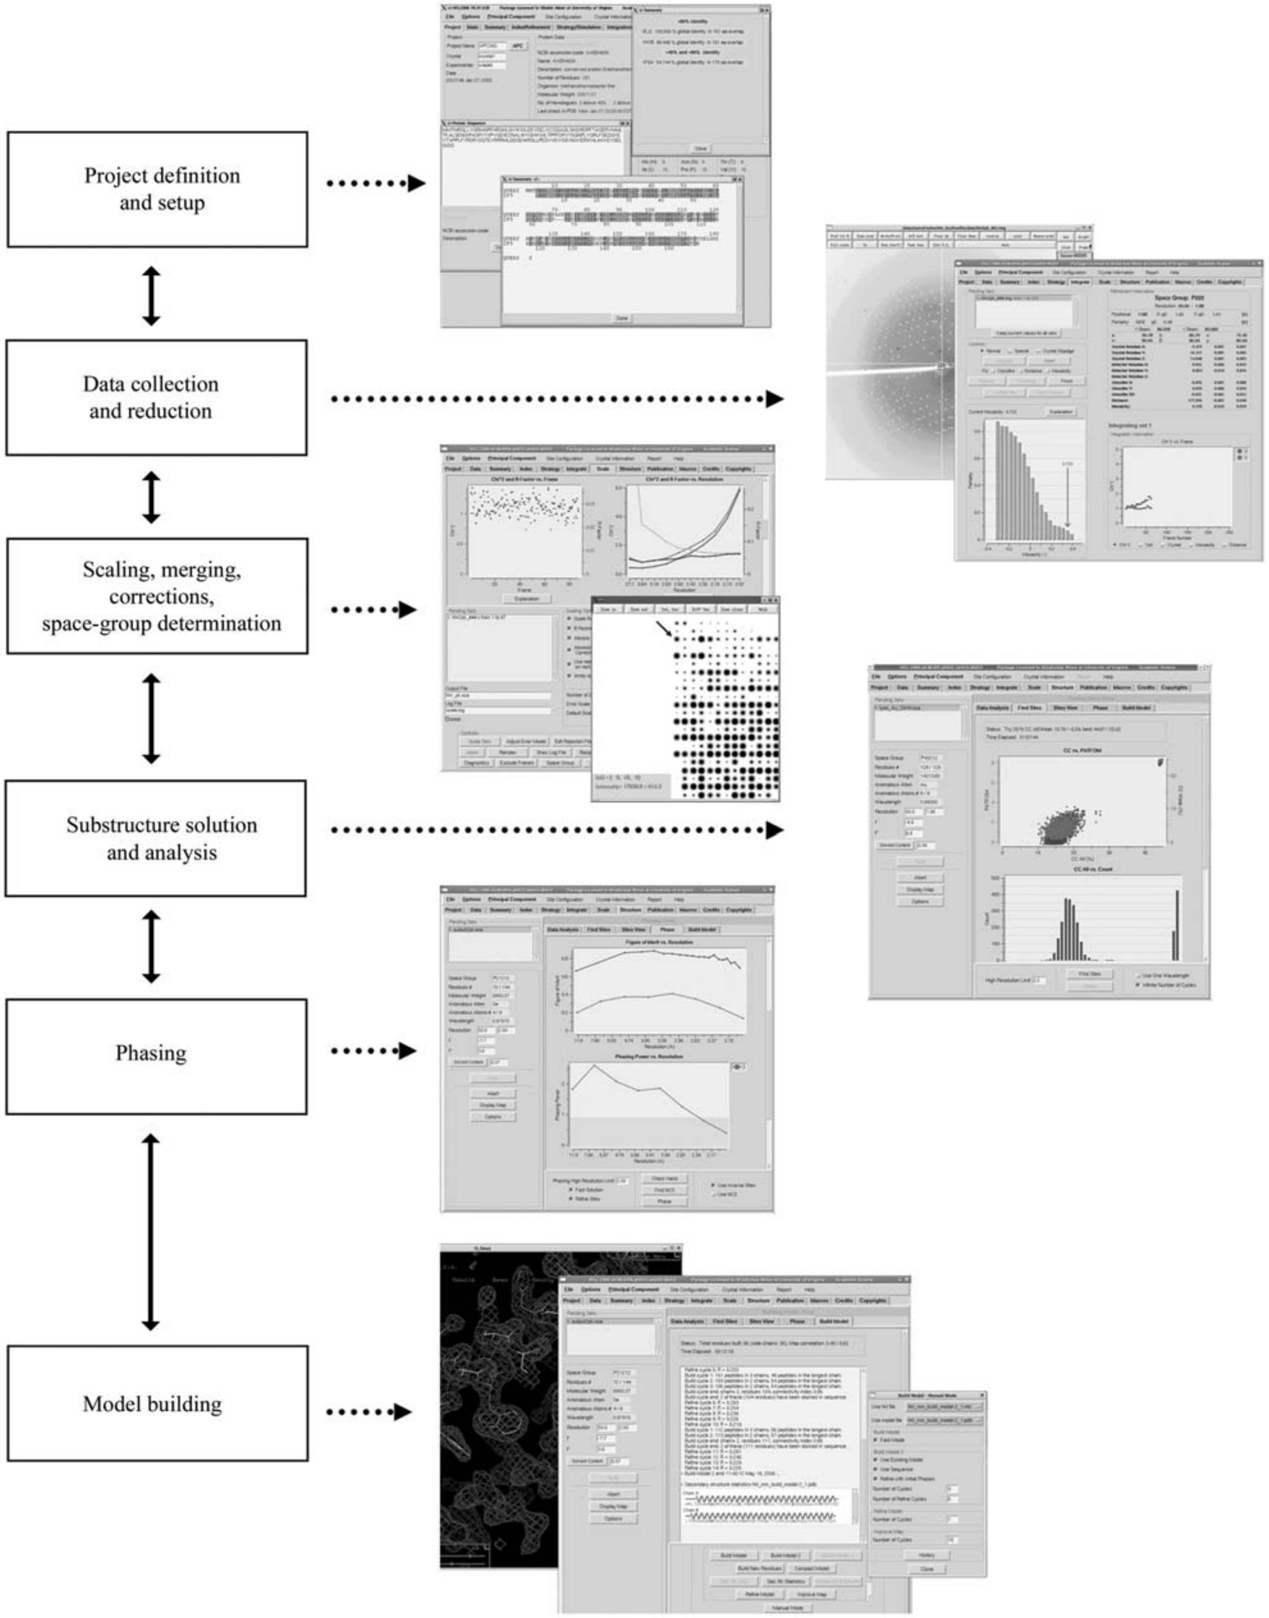
DENZO and *SCALEPACK* form the numerical processing core of the *HKL* package. These programs can be used directly by editing commands in input scripts, but most of the time they are run through *HKL-2000* and its more expanded version *HKL-3000*.

The basic mode of *HKL-2000* reads in previously collected data as input and produces scaled and merged reflections as output. This use can be extended in three directions: control of the data-collection process by *HKL-2000* and *HKL-3000* (Minor *et al.*, 2002, 2006), incorporation of methods of structure solution by *HKL-3000* (Minor *et al.*, 2006), and storage of critical intermediate results in an external database (Grabowski *et al.*, 2007).

Crystallographic structure determinations encompass a wide range of project dynamics. There are many projects where all the steps are executed serially, while others involve substantial iterative improvements, where one or a few stages are repeated a number of times. *HKL-2000* and *HKL-3000* are designed to make both types of project more effective. To accomplish this, information is automatically propagated between various stages of analysis, and many necessary data transformations are performed to accommodate the interface requirements of many programs and beamline controls. At the same time, crystallography requires the experimenter to be actively engaged in decision making, depending on the nature of a particular project and types of problems encountered. The experimenter may need to assess the quality of a set of crystals, decide how to collect data sets from a chosen subset, determine the symmetry of each diffraction pattern, reassess the crystal quality based on the integration and merging steps, and then solve the structure using an appropriate method. Not all programs are fully automatic, and the experimenter may need to be involved in defining how a particular procedure should be executed. As a consequence, both *HKL-2000* and *HKL-3000* have a multiplicity of interface screens (accessed by tabs in the graphical control centre), each of them designed to control a particular process.

The versions of *HKL-2000* and *HKL-3000* that interface with data-collection systems can coordinate all parameters of the diffraction experiment. This facilitates interactive experiments in which data analysis is done online and results are automatically updated when new data are collected. In such experiments, it is possible to adjust the data-collection strategy to guarantee the desired result, particularly with regard to data completeness. The strategy takes into account limitations arising from radiation damage. Radiation damage can be estimated from past experience with similar crystals, by theoretical calculations of decay based on beam intensity, and by evaluating scale- and B-factor changes in real time.

The graphical control centre of *HKL-2000* (and *HKL-3000*) consists of three components: an internal database (optionally connected to an external one), a transition-state engine and a graphical user interface (GUI). The internal database stores all the information about data processing and data collection. It can describe not only the data already collected, but also those being collected and even those planned for collection. Each datum entered or program executed, including the data-collection interface, induces a change in the database by the transition-state engine. One of the main functions of the GUI is input to and



Project definition and setup
Data collection and reduction
Scaling, merging, corrections, space-group determination
Substructure solution and analysis
Phasing
Model building

Figure 11.4.12.1
General layout of *HKL-3000*. The experimenter is not limited to movement between neighbouring steps. For example, using feedback from model building, one can decide to collect more data (for example, a second wavelength or a low-resolution pass) and jump directly back to the 'Data collection and reduction' step.

editing of the database. The other major function is generation of reports from the database (to visualize its status).

The internal database abstraction is based on the following hierarchy: instrument type; site; experiment; crystal; three-dimensional (3D) group of diffraction images; and diffraction image. Each lower level of the hierarchy inherits the properties of the higher levels. When a program finishes analysing data at a particular level, the parent (higher-level) data are updated, so that data at the same level communicate only through the change of state of their common parent. The site-level data are created only when diffraction from a new detector is seen or when the parameters of the detector are changed, which is done rarely and typically by the X-ray equipment administrator. The experiment-level data describe diffraction data from one or more crystals of the same space group. A uniform series of diffraction images form 3D groups. There is no limit to the number of 3D groups, and, in the case of non-uniformity in the series (*e.g.* as found during data analysis), one 3D group can be split into two or more smaller 3D groups. The smallest 3D group can consist of one image. A crystal datum contains a set of 3D groups with a relative orientation and exposure level known *a priori*. In practice, this means that diffraction data encapsulated within a single crystal datum were collected from one sample at one site with potentially different settings of goniostat, data-collection axis, crystal translation, detector position, detector mode (*e.g.* binned/unbinned) or exposure level.

HKL-3000 combines a number of existing macromolecular crystallographic computer programs [*SHELX* (Sheldrick, 2008), *CCP4* (Collaborative Computational Project, No. 4, 1994), *SOLVE/RESOLVE* (Terwilliger, 2004), *ARP/wARP* (Perrakis *et al.*, 1999) and *COOT* (Emsley & Cowtan, 2004)] and decision-making algorithms into a powerful expert system (Fig. 11.4.12.1). The typical end result of *HKL-3000* is an interpretable electron-density map with a partially built structure and, in some cases, an almost complete and refined model.

The *HKL-3000* system is designed to evaluate the results of laboratory and synchrotron diffraction experiments very quickly. The system supports most common types of macromolecular crystallography experiments: isomorphous (IR) and molecular replacement (MR), multiple anomalous diffraction (MAD)/single anomalous diffraction (SAD), and native data collection for high-resolution refinement of previously solved models of proteins or protein–ligand complexes. SAD experiments have became popular in recent years (Chruszcz *et al.*, 2008) at least partly due to development of integrated systems like *HKL-3000*, which allow the experimenter to validate whether experimental data collected at one wavelength are of sufficient quality to solve the structure. The concurrent data collection, data processing and quick preliminary structure solution made by *HKL-3000* verifies the success of the X-ray experiment and allows optimization of the data-collection strategy while the crystal is still on the goniostat. This allows the experimenter to decide whether the experiment has been successfully completed and thus whether the crystal can be removed.

11.4.13. Final note

The methods presented here have been used to solve tens of thousands of crystal structures deposited in public data repositories. The results range from crystal structures of inorganic molecules with 3 Å unit-cell parameters to a crystal structure of a 700 Å-diameter virus, which crystallized in a 700 × 1000 × 1400 Å unit cell. The precision of signal estimation was sufficient to determine a structure where the amplitudes of the imaginary Bijvoet components were approximately 0.15% of the total amplitudes (Borek *et al.*, 2007), and for the results of integration and scaling analyses to be used in charge-density studies (Dominiak *et al.*, 2006). The success of these methods is a consequence of the robust and stable implementation described above.

This work was supported by NIH grant GM-53163. We would like to acknowledge the contributions of the many researchers who provided us with diffraction data representing a wide range of experimental problems. We are indebted to the following people who developed other diffraction-data-analysis programs, interactions with whom contributed to *HKL* program development and to the ideas presented here: M. G. Rossmann, G. Bricogne, P. Evans, A. Howard, W. Kabsch, A. Leslie, J. Pflugrath and G. Sheldrick. We would also like to thank H. Czarnocka, R. Henderson, W. Majewski, A. Pertsemlidis, D. Tomchick and M. Zimmerman for help in preparing this manuscript.

Chapter 11.5. The use of partially recorded reflections for post refinement, scaling and averaging X-ray diffraction data

C. G. van Beek, R. Bolotovsky and M. G. Rossmann

11.5.1. Introduction

Recent advances in the use of frozen crystals of biological samples for X-ray diffraction data collection (Rodgers, 1994) often result in data for which most of the observed reflections on each frame are partially observed. This might be avoided by increasing the oscillation ranges, but this would cause many reflections to overlap with their neighbours. Hence, it is necessary to develop scaling procedures that are independent of the exclusive use of fully recorded reflections.

A set of measured Bragg intensities is dependent on the properties of the crystal, radiation source and detector. Usually, these factors cannot be kept constant throughout the data collection. The crystal may decay, weakening the Bragg intensities, or even 'die', which requires the use of several crystals for a full data set. The intensity and position of the primary X-ray beam may vary, especially at synchrotron-radiation sources. Finally, the detector response may change when, for example, different films or imaging plates are used during the data collection.

Most data sets can be divided into series of subsets, or frames, collected under more-or-less constant conditions. These frames need to be placed on a common arbitrary scale. The scaling can be performed by comparing the intensities of multiply measured reflections or symmetry-equivalent reflections on different frames.

A least-squares procedure frequently used for scaling frames of data is the Hamilton, Rollett and Sparks (HRS) method (Hamilton *et al.*, 1965). The target for the HRS least-squares minimization is

$$\psi = \sum_h \sum_i W_{hi}(I_{hi} - G_m I_h)^2, \qquad (11.5.1.1)$$

where I_h is the best estimate of the intensity of a reflection with reduced Miller indices h, I_{hi} is the intensity of the ith measurement of reflection h, W_{hi} is a weight for reflection h_i and G_m is the inverse linear scale factor for frame m on which reflection h_i is recorded. The reduced Miller indices are those corresponding to an arbitrarily defined asymmetric unit of reciprocal space. The HRS expression (11.5.1.1) assumes that all reflections h_i are full, that is, their reciprocal-lattice points have completely passed through the Ewald sphere.

For all unique reflections h, the values of I_h must correspond to a minimum in ψ. Thus,

$$\partial\psi/\partial I_h = 0. \qquad (11.5.1.2)$$

Therefore, the best least-squares estimate of the intensity of a reflection is

$$I_h = \sum_i W_{hi} G_m I_{hi} \Big/ \sum_i W_{hi} G_m^2. \qquad (11.5.1.3)$$

Since ψ is not linear with respect to the scale factors G_m, the values of the scale factors have to be determined by an iterative nonlinear least-squares procedure. As the scale factors are relative to each other, the HRS procedure requires that one of them be fixed.

Fox & Holmes (1966) describe an improved method of solving the HRS normal equations. Their approach is based on the singular value decomposition of the normal equations matrix. The advantage of the Fox and Holmes method, apart from the accelerated convergence of the least-squares procedure, is that no *ad hoc* decision needs to be made as to which scale factor should be fixed. Furthermore, 'troublesome' frames of data can be identified as causing negligibly small eigenvalues in the normal equations matrix.

11.5.2. Generalization of the Hamilton, Rollett and Sparks equations to take into account partial reflections

When a Bragg reflection is completely exposed within the oscillation range of one frame, a so-called 'full reflection', it gives rise to the 'full intensity'. In general, a Bragg reflection will occur on a number of consecutive frames as a series of partial reflections, and the full intensity can only be estimated from the measured intensities of the partial reflections. Let I_{him} represent the intensity contribution of reflection h_i recorded on frame m; if all the parts of h_i are available in the data set, then

$$I_{hi} = \sum_m (I_{him}/G_m). \qquad (11.5.2.1)$$

In practice, there will always be reflections that do not have all their parts available. In such cases, the only way to estimate the full intensity of a reflection is to apply an estimated value of the partiality to the measured reflection intensities.

Various models have been proposed to calculate the reflection partiality. Here we use Rossmann's model (Rossmann, 1979; Rossmann *et al.*, 1979) with Greenhough & Helliwell's (1982) correction. This model treats partiality as a fraction of a spherical volume swept through the Ewald sphere. The coordinates of the reciprocal-lattice point are defined by the Miller indices of the reflection, the crystal orientation matrix and the rotation angle. The volume of the sphere around the reciprocal-lattice point accounts for crystal mosaicity and beam divergence. Alternative geometrical descriptions of a reciprocal-lattice point passing through the Ewald sphere have been given by Winkler *et al.* (1979) and Bolotovsky & Coppens (1997).

Provided the reflection partiality, p_{him}, is known, the full intensity is estimated by

$$I_{hi} = I_{him} \big/ p_{him} G_m. \qquad (11.5.2.2)$$

This expression can produce as many estimates of I_{hi} as there are parts of reflection h_i, while expression (11.5.2.1) produces only one estimate of I_{hi} when all parts of reflection h_i are recorded. Having defined the relationships between measured intensities of partial reflections and estimated full reflections by expressions (11.5.2.1) and (11.5.2.2), two methods of generalizing the HRS equations can be considered.

Method 1. If a reflection h_i occurs on a number of consecutive frames and all parts of I_{him} are available in the data set, the generalized HRS target equation takes the form

Copyright © 2012 International Union of Crystallography

$$\psi = \sum_h \sum_i \sum_m W_{him} \left\{ I_{him} - G_m \left[I_h - \sum_{m' \neq m} (I_{him'} / G_{m'}) \right] \right\}^2 . \tag{11.5.2.3}$$

Using expression (11.5.1.2), the best least-squares estimate of I_h will be

$$I_h = \frac{\sum_i \left[\sum_m (I_{him}/G_m) \right] \left(\sum_m W_{him} G_m^2 \right)}{\sum_i \sum_m W_{him} G_m^2} = \frac{\sum_i I_{hi} \sum_m W_{him} G_m^2}{\sum_i \sum_m W_{him} G_m^2} . \tag{11.5.2.4}$$

Method 2. If the theoretical partiality, p_{him}, of the partially recorded reflection h_{im} can be estimated, the generalized HRS target equation takes the form

$$\psi = \sum_h \sum_i \sum_m W_{him} (I_{him} - G_m p_{him} I_h)^2 \tag{11.5.2.5}$$

and, using expression (11.5.1.2), the best least-squares estimate of I_h will then be

$$I_h = \frac{\sum_i \sum_m W_{him} G_m p_{him} I_{him}}{\sum_i \sum_m W_{him} G_m^2 p_{him}^2} . \tag{11.5.2.6}$$

When all reflections in the data set are fully recorded, expressions (11.5.2.3) and (11.5.2.5) reduce to the 'classical' HRS expression (11.5.1.1), and expressions (11.5.2.4) and (11.5.2.6) reduce to expression (11.5.1.3).

The scale factor G_m can be generalized to incorporate crystal decay (Gewirth, 1996; Otwinowski & Minor, 1997):

$$G_{him} = G_m \exp\left\{ -2B_m \left[\sin(\theta_{hi})/\lambda \right]^2 \right\}, \tag{11.5.2.7}$$

where B_m is a parameter describing the crystal disorder while frame m was recorded, θ_{hi} is the Bragg angle of reflection h_i and λ is the X-ray wavelength.

Method 1 only allows the refinement of the scale factors while method 2 allows refinement of the scale factors, crystal mosaicity and orientation matrix, as the latter two factors contribute to the calculated partiality. Furthermore, method 2 is essential for scaling of data sets with low redundancy (*e.g.* data collected from low-symmetry crystals or data collected over small rotation ranges). When a reflection h_i spans more than one frame, but there are no other reflections with the same reduced Miller indices h in the data set, the contribution of any partial reflection h_{im} to expression (11.5.2.3) will be zero, as in this case I_h will be the same as I_{hi}. In contrast, in method 2 the reflection h_i can be used for scaling because the estimates of the full intensity I_{hi} are calculated independently from every frame spanned by reflection h_i.

11.5.3. Selection of reflections useful for scaling

Both scaling methods 1 and 2 may take into account any reflection intensity observation, regardless of whether it is a partially or fully recorded reflection. However, there are significant differences between the selection of reflections in the two methods. Method 1 requires that all parts of a reflection are available in order to incorporate the reflection into the generalized HRS target, expression (11.5.2.3). Thus, reflections that occur at the beginning or the end of the crystal orientation, or at gaps within the rotation range, must be rejected. Even when all parts of a reflection are recorded, there might be parts for which there was a problem during integration, thus making the reflection useless for scaling. The decision on whether all parts of a reflection are available for scaling is dependent on knowledge of the crystal mosaicity and of the crystal orientation matrix. Since these might be inaccurate, a reasonable tolerance has to be exercised when deciding if a reflection has been completely measured on consecutive frames. Method 2 allows the use of all reflections for scaling as every observation of a partial reflection is sufficient to estimate the intensity of a full reflection, expression (11.5.2.2). However, a reasonable lower limit of calculated partiality has to be imposed in selecting reflections useful for scaling. The criteria for rejecting reflections prior to scaling and averaging are listed in Table 11.5.3.1.

11.5.4. Restraints and constraints

Scale factors will depend on the variation of the incident X-ray beam intensity, crystal absorption and radiation damage. Hence, in general, scale factors can be constrained to follow an analytical function or restrained to minimize variation between successive frames. The scale factors can be restrained by adding a term $w(G_n - G_{n+1})^2$ to ψ, expression (11.5.1.1), where G_n and G_{n+1} are scale factors for the nth and $(n+1)$th frame and w is a suitably chosen weight. Such procedures will increase $R_{\rm merge}$ but will also increase the accuracy of the scaled intensities as additional reasonable physical conditions have been applied.

The mis-setting angles of a single crystal should remain constant throughout the data set. Thus, in principle, the mis-setting angles should be constrained to be the same for all frames associated with a single crystal in the data set. However, in practice, independent refinement of the mis-setting angles can detect problems in the data set when there are discontinuities in

Table 11.5.3.1

Hierarchy of criteria for selecting reflections for scaling and averaging procedures

<table>
<tr><td colspan="2">Methods 1 and 2</td></tr>
<tr><td colspan="2">All parts of a reflection are rejected if:
(1) There are no successfully integrated parts.
(2) There are no parts with significant intensity (for scaling only).
(3) There are some parts entering and some parts exiting the Ewald sphere (this implies that the reflection is too close to the rotation axis and is partly in the blind zone).
(4) This is a full reflection recorded only once with no other symmetry-equivalent observations.</td></tr>
<tr><td>Method 1</td><td>Method 2</td></tr>
<tr><td>All parts of a reflection are rejected if:
(1) There is a part that is not successfully integrated.
(2) There is a part that has a significant intensity, but is not predicted by the crystal orientation and mosaicity used in the scaling program.
(3) The sum of calculated partialities differs from unity by more than a chosen value.</td><td>Any part of a reflection is rejected if:
(1) The calculated partiality is less than a chosen value.
(2) The intensity is less than a chosen fraction of the error estimate.</td></tr>
</table>

these angles with respect to frame number. Cell dimensions should be the same for all crystals and might therefore be constrained. However, care should be taken, as the exact conditions of freezing may cause some variations in cell dimensions between crystals. As radiation damage proceeds, mosaicity is likely to increase. Hence, constraint between the refined mosaicities of neighbouring frames can be useful.

11.5.5. Generalization of the procedure for averaging reflection intensities

Once the scale factors of all frames are determined, they need to be applied to the reflection intensities and error estimates. The reflection intensities with the same reduced Miller indices can then be averaged.

When method 2 is used for averaging, the determination of $\langle I_h \rangle$ is more complicated as there are as many estimates of the full intensity I_{hi} as there are partial reflections h_{im}. Therefore, intensity averaging of reflection h has to be done in two steps. First, for every reflection h_i, the intensity estimates from all partial observations will be the weighted mean, where the weights are based on the estimated standard deviations of each intensity measurement. In the second step, the average is taken over the i different scaled intensities for the observed reflections.

The selection of reflections useful for averaging is the same as for scaling (Table 11.5.3.1), except that it is no longer necessary to reject reflections that have insignificant intensities. Applying a σ cutoff while averaging the scaled intensities will lead to a statistical bias of the weaker reflection intensities.

For samples of three or more equivalent reflections, it is necessary to consider the absolute values of the differences between individual intensities and the median of the sample: $|I_{hi} - I_{\rm median}|$. The outliers can be detected by several statistical tests and, once detected, can be either down-weighted or rejected. When the sample consists of only two reflections, they can be considered a ‘discordant pair’ if the difference between their intensities is not warranted by the estimated errors and, hence, both reflections can be rejected (Blessing, 1997).

Averaging intensities estimated according to method 2 has an advantage over method 1 as outliers and discordant pairs can be ‘screened’ at two levels: firstly, when the estimates of the full reflection intensity I_{hi}, calculated by expression (11.5.2.2) from different parts of the same reflection, are considered, and secondly when the mean intensities $\langle I_{hi} \rangle$ from different reflections are considered.

11.5.6. Estimating the quality of data scaling and averaging

A commonly used estimate of the quality of scaled and averaged Bragg reflection intensities is $R_{\rm merge}$. Useful definitions of R factors are:

$$R_{\rm merge} = \quad R_1 = \left[\left(\sum_h\sum_i |I_{hi} - \langle I_h \rangle|\right)\Big/\sum_h\sum_i |I_{hi}|\right] \times 100\%, \qquad (11.5.6.1)$$

$$R_2 = \left\{\left[\sum_h\sum_i (I_{hi} - \langle I_h \rangle)^2\right]\Big/\sum_h\sum_i I_{hi}^2\right\} \times 100\% \qquad (11.5.6.2)$$

and

$$R_w = \left\{\left[\sum_h\sum_i W_{hi}(I_{hi} - \langle I_h \rangle)^2\right]\Big/\sum_h\sum_i W_{hi} I_{hi}^2\right\} \times 100\%. \qquad (11.5.6.3)$$

The linear (R_1), square (R_2) and weighted (R_w) R factors can be subdivided into resolution ranges, intensity ranges, reflection classes, frame number and regions of the detector surface. When method 1 is used, reflections h_i can be grouped in terms of the sums of partialities of contributing partial reflections h_{im}.

The R-factor variation depends on the properties of the detector with respect to intensities. Generally the R factor decreases as intensity increases. Thus, the R factor generally increases with resolution. Any deviation from this behaviour might indicate a problem in the data collection due to nonlinearity of the detector response, ice diffuse diffraction, or any other stray effects superimposed on the crystal diffraction.

A useful indicator of the quality of the intensity estimates of partial reflections is the mean ratio of calculated partiality to observed partiality:

$$r_p = \langle p_{him}^{\rm calc}/p_{him}^{\rm obs} \rangle = \langle p_{him}^{\rm calc} \langle I_h \rangle / I_{him} \rangle. \qquad (11.5.6.4)$$

The deviation of this ratio from unity can be examined as a function of the reflection intensity, resolution and calculated partiality.

The comparison of R factors for centric and noncentric reflections can be used to determine the significance of an anomalous-scattering effect. The quality of the anomalous-dispersion signal can be assessed by calculation of the scatter, σ_{Ih}, where

$$\sigma_{Ih} = \left\{[1/(n-1)]\sum_n (\langle I_h \rangle - I_{hn})^2\right\}^{1/2} \qquad (11.5.6.5)$$

and $\langle I_h \rangle$ is the average of the n measurements of the full reflection intensities I_{hn}. The σ_{Ih} values for noncentric reflections can be compared to the scatter, σ_{Ih}^+ or σ_{Ih}^-, of reflections differing only in absorption while excluding Bijvoet opposites. The mean scatter is calculated from all σ_{Ih} values,

$$\langle \sigma_{Ih} \rangle = (1/h)\sum_h \left\{[1/(n-1)]\sum_n (\langle I_h \rangle - I_{hn})^2\right\}^{1/2}. \qquad (11.5.6.6)$$

The ratios $\langle \sigma_{Ih} \rangle / \langle \sigma_{Ih}^+ \rangle$ and $\langle \sigma_{Ih} \rangle / \langle \sigma_{Ih}^- \rangle$ should be larger than unity for significant anomalous-dispersion data.

11.5.7. Experimental results

11.5.7.1. Variation of scale factors versus frame number

If scale factors are to make physical sense, their behaviour with respect to the frame number has to be in accordance with the known changes in the beam intensity, crystal condition and detector response.

The scaling of a φX174 procapsid data set (Dokland *et al.*, 1997) was performed using methods 1 and 2 as described here and using *SCALEPACK* (Otwinowski & Minor, 1997) (Fig. 11.5.7.1). Graphs (*a*) and (*b*) in Fig. 11.5.7.1 have four segments corresponding to four synchrotron beam ‘fills’. All three methods give scale factors within 5% of each other (Figs. 11.5.7.1*c* and *d*). However, for the first and last frame of each ‘fill’ the results can differ by as much as 15%. Both method 1 and *SCALEPACK* produce physically wrong results in that the scale factors of these frames look like outliers compared to the scale factors of the neighbouring frames. By contrast, method 2 provides consistent scale factors for these frames. Although the algorithm used by *SCALEPACK* for scaling frames with partial reflections has never been disclosed, the similar results obtained by method 1 and *SCALEPACK* suggest that *SCALEPACK* might be using an algorithm similar to that of method 1 (Fig. 11.5.7.1*d*).

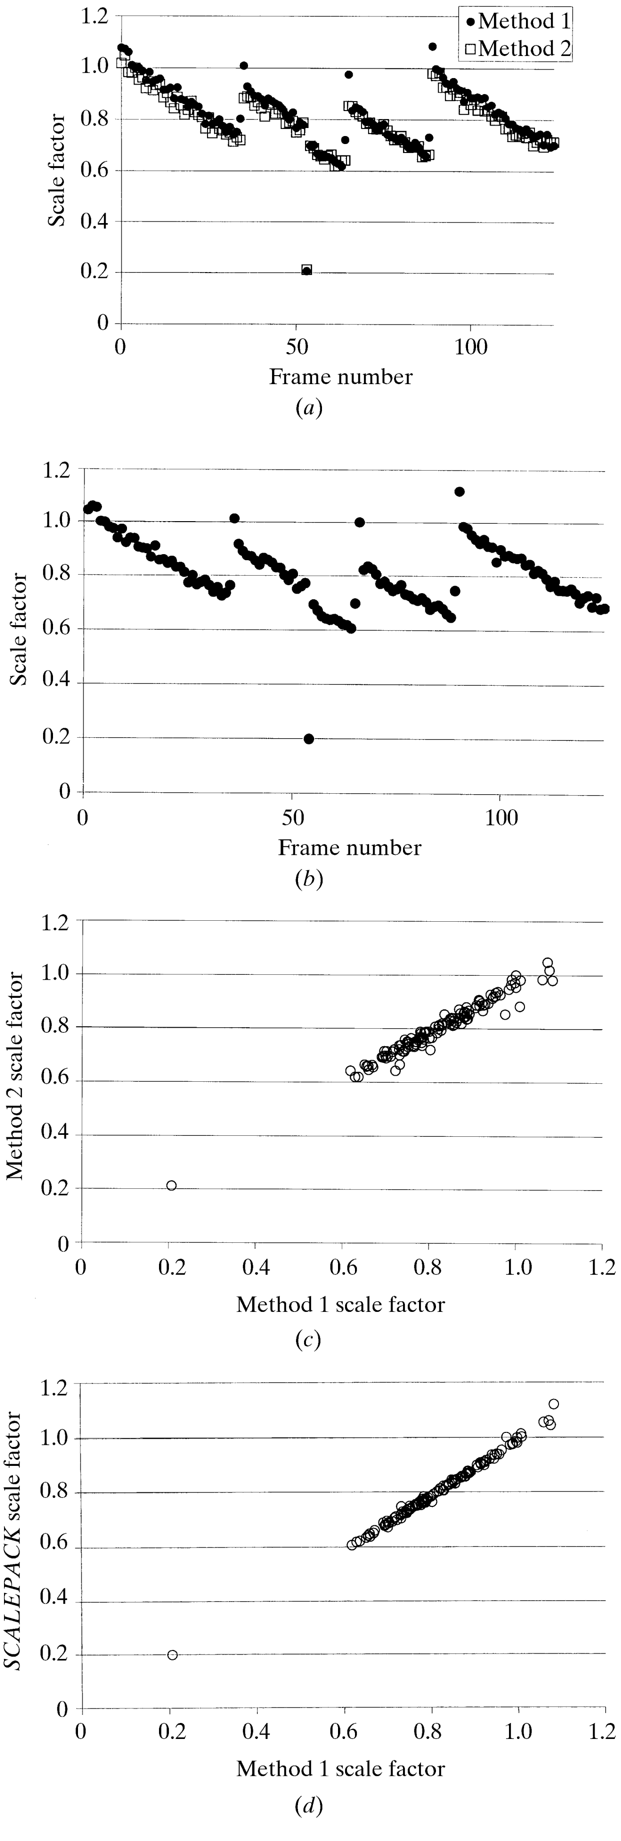

Figure 11.5.7.1

Linear scale factors as a function of frame number for a φX174 data set (Dokland *et al.*, 1997). Results from (*a*) method 1 and method 2, (*b*) *SCALEPACK*. Comparison of (*c*) method 2 *versus* method 1, and (*d*) *SCALEPACK versus* method 1.

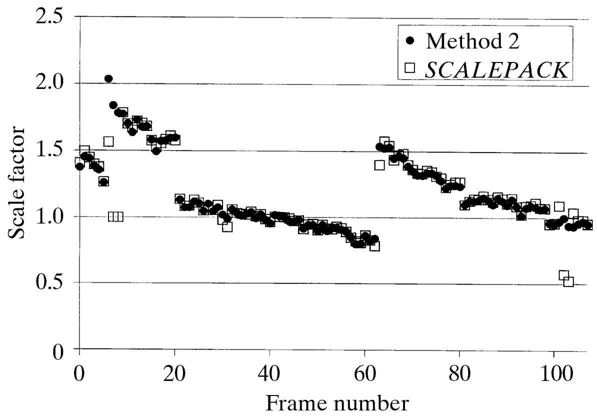

Figure 11.5.7.2

Linear scale factor as a function of frame number for an HRV14 data set (Rossmann *et al.*, 1985, 1997).

Attempts at scaling a data set of a frozen crystal of HRV14 (Rossmann *et al.*, 1985, 1997) failed with method 1 as a result of gaps in the rotation range for the first 20 frames, causing singularity of the normal equations matrix. When frames without useful neighbours were excluded, the cubic symmetry of the crystal was sufficient for successful scaling. In contrast, method 2 did not have any problems with the whole data set, and the results obtained with method 2 showed greater consistency than those obtained with method 1 or *SCALEPACK* (Fig. 11.5.7.2).

The accuracy and robustness of method 2 is also demonstrated by the scaling results for a Sindbis virus capsid protein (SCP), residues 114–264 (Choi *et al.*, 1991, 1996). The behaviour of the scale factor with respect to the frame number reflects the anisotropy of the thin plate-shaped crystal (Fig. 11.5.7.3). For the first 40 frames (frame numbers 0 to 39), even-numbered frames have higher scale factors than odd-numbered frames. Data collection was stopped after frame number 39 and restarted. After frame number 39, odd-numbered frames have higher scale factors than even-numbered frames. This effect presumably relates to the use of the two alternating image plates with slightly different sensitivities in the *R*-axis camera used in the data collection.

11.5.7.2. *R factor as a function of 'sum-of-partialities' (method 1)*

In order to determine the limits of tolerance that can be permitted when method 1 is used, the *R* factor was examined as a

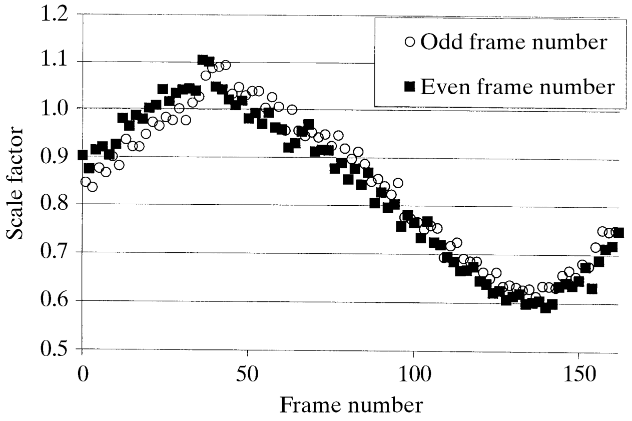

Figure 11.5.7.3

Linear scale factor determined by method 2 as a function of frame number for an SCP(114–264) data set (Choi *et al.*, 1991, 1996). The sine-like pattern reflects the anisotropy of a thin plate-shaped crystal.

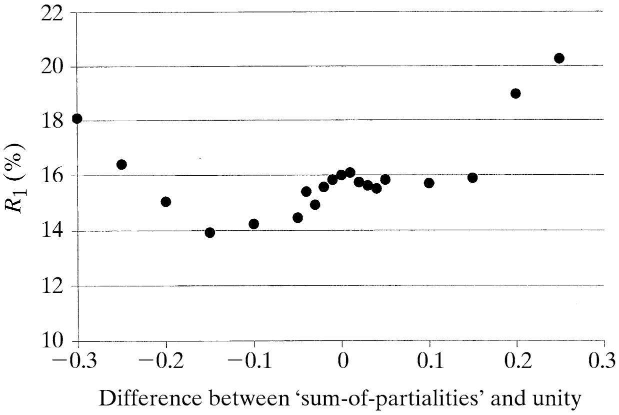

Figure 11.5.7.4
R factor as a function of the difference of calculated 'sum-of-partialities' and unity for the estimates of full reflections when method 1 is used for the scaling and averaging of a φX174 data set (Dokland *et al.*, 1997).

function of the sum-of-partialities for the φX174 procapsid data (Fig. 11.5.7.4). Reflections with sum-of-partialities of 1 ± 0.3 were used. The R factor changes sharply when the sum-of-partialities is outside 1 ± 0.15. Hence, ± 0.15 were acceptable limits of tolerance for this data set.

11.5.7.3. *Statistics for rejecting reflections and data quality as a function of frame number*

The behaviour of the R factor *versus* frame number (Fig. 11.5.7.5) is more monotonic when method 1 is used compared to method 2. In method 1, the data-quality estimates for neighbouring frames are strongly correlated because the full reflections used in the statistics are obtained by summing partials from consecutive frames. By contrast, in method 2 every frame produces estimates of full reflection intensities independently of the neighbouring frames. Therefore, the R factors per frame calculated after scaling with method 2 truly represent the data quality for individual frames.

11.5.7.4. *Observed versus calculated partiality*

The relationship between observed and calculated partialities (Fig. 11.5.7.6) deviates from the ideal line $p_{\rm obs} = p_{\rm calc}$, especially for the smaller calculated partialities where $p_{\rm obs} > p_{\rm calc}$. This suggests errors in the measurements of $p_{\rm obs}$ or the calculations of $p_{\rm calc}$. The latter may be improved by a post refinement of the orientation matrix and crystal mosaicity (Rossmann *et al.*, 1979).

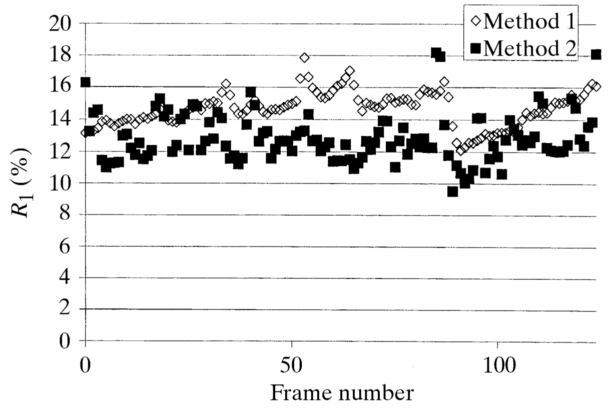

Figure 11.5.7.5
R factor per frame as a function of frame number for a φX174 data set (Dokland *et al.*, 1997).

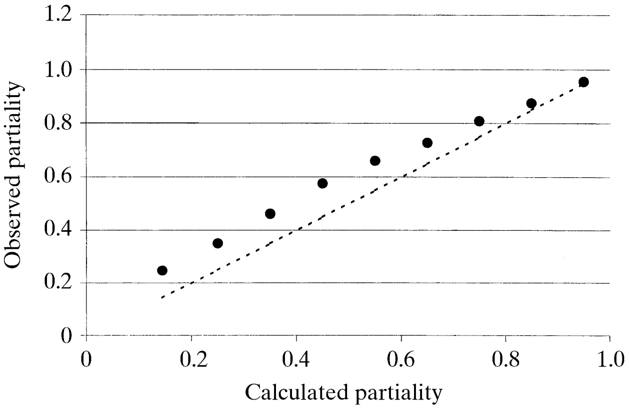

Figure 11.5.7.6
The observed partialities plotted against calculated partialities for a φX174 data set (Dokland *et al.*, 1997) processed by method 2. The observed partialities for individual partial reflections were averaged in bins of calculated partialities. The broken line represents the ideal relationship $p_{\rm obs} = p_{\rm calc}$.

11.5.7.5. *Anisotropic mosaicity*

Refinement of the effective mosaicity can show both the anisotropic nature of the crystal (Fig. 11.5.7.7) as well as the impact of radiation damage. The effective mosaicity is the convolution of the mosaic spread of the crystal, the beam divergence and the wavelength divergence of the incident X-ray beam. Hence, X-ray diffraction data collected at a synchrotron-radiation source necessitate the differentiation of the effective mosaicity in the horizontal and vertical planes. A more general approach is the introduction of six parameters reflecting the anisotropic effective mosaicity.

11.5.7.6. *Anomalous dispersion*

The quality of anomalous-dispersion data can be assessed by calculation of the average scatter, expression (11.5.6.6). The ratios $\langle \sigma_{Ih} \rangle / \langle \sigma^{+}_{Ih} \rangle$ and $\langle \sigma_{Ih} \rangle / \langle \sigma^{-}_{Ih} \rangle$ should be larger than unity for significant anomalous data (Fig. 11.5.7.8). Note the much larger ratios for the scatter among measurements of I_h for data measured at the absorption edge of Se, as opposed to measurements remote from the edge. The decreasing values of the ratios with resolution are due to the decrease of I_h value, thus causing

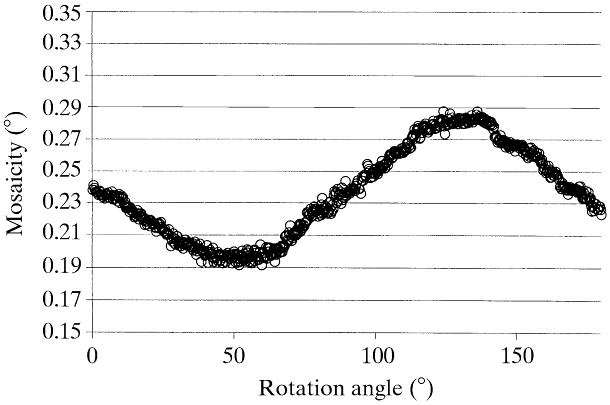

Figure 11.5.7.7
Variation of (unconstrained) mosaicity for a monoclinic crystal of the bacterial virus alpha3 (Bernal *et al.*, 1998) showing the crystal anisotropy.

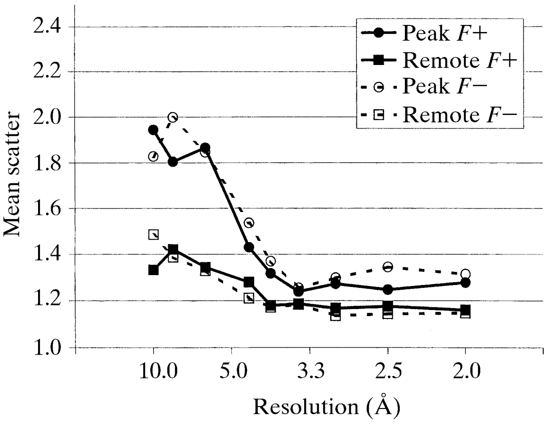

Figure 11.5.7.8
Quality of anomalous-dispersion data for an SeMet derivative of dioxygenase Rieske ferredoxin (Colbert & Bolin, 1999).

the error in the measurement of I_h to approach the difference in intensity of Bijvoet opposites.

11.5.8. Conclusions

The generalized HRS method allows scaling and averaging of X-ray diffraction data collected with an oscillation camera while simultaneously using full and partial reflections. The procedure is as useful for thin slices of reciprocal space as it is for thicker slices.

The results of data processing with the two different algorithms indicate that method 1, based on adding partial reflections, may fail to scale data sets with gaps in the rotation range or with low redundancy. The values of the scale factors obtained with both methods are similar, except for cases where there are gaps in the rotation range or dramatic changes in the true scale factors between consecutive frames. In these cases, method 1 produces a physically wrong result. The algorithm used by method 1 is probably similar to that used by *SCALEPACK* (Otwinowski & Minor, 1997).

Method 2 is more stable and versatile than method 1, and allows the scaling of data sets with incompletely measured reflections and low redundancy. The major drawback of method 2 is that errors in the crystal orientation matrix and mosaicity, as well as inadequacies of the theoretical model for reflection partiality, contribute to errors in the scaled intensities. Therefore, post refinement is needed for method 2 to perform at its best.

APPENDIX A11.5.1

Partiality model (Rossmann, 1979; Rossmann *et al.*, 1979)

Small differences in the orientation of domains within the crystal, as well as the cross fire of the incident X-ray beam, will give rise to a series of possible Ewald spheres. Their extreme positions will subtend an angle $2m$ at the origin of the reciprocal space, and their centres lie on a cusp of limiting radius $\delta = m/\lambda$, where m is the half-angle effective mosaic spread. As the reciprocal lattice is rotated around the axis (Oy) perpendicular to the mean direction of the incident radiation (Oz), a point P will gradually penetrate the effective thickness of the reflection sphere (Fig. A11.5.1.1). Initially, only a few domain blocks will satisfy Bragg's law, but upon further rotation the number of blocks that are in a reflecting condition will increase. The maximum will be reached when the point P has penetrated halfway through the sphere's effective thickness, after which there will be a decline of the crystal volume able to diffract.

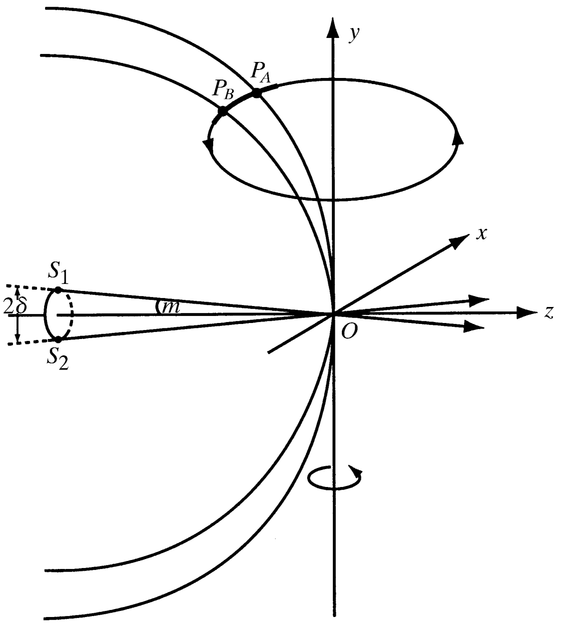

Figure A11.5.1.1
Penetration of a reciprocal-lattice point P into the sphere of reflection by rotation around Oy. The extremes of reflecting conditions at P_A and P_B are equivalent to X-rays passing along the lines S_1O and S_2O with centres of the Ewald spheres at S_1 and S_2 and subtending an angle of $2m$ at O. Hence, in three dimensions, the extreme reflecting spheres will lie with their centres on a circle of radius $\delta = m/\lambda$ at $z = -1/\lambda$.

Let q be a measure of the fraction of the path travelled by P between the extreme reflecting positions P_A and P_B, and let p be the fraction of the energy already diffracted. Then the relation between p and q must have the general form shown in Fig. A11.5.1.2. It is physically reasonable to assume that the curve for p is tangential to $q = 0$ at $p = 0$ and to $q = 1$ at $p = 1$.

A reasonable approximation to the above conditions can be obtained by considering the fraction of the volume of a sphere removed by a plane a distance q from its surface (Fig. A11.5.1.2). It is easily shown that if p is the volume, then

$$p = 3q^2 - 2q^3. \qquad \text{(A11.5.1.1)}$$

This curve is shown in Fig. A11.5.1.2 and corresponds to assuming that the reciprocal-lattice point is a sphere of finite volume cutting an infinitely thin Ewald sphere. Also shown in Fig. A11.5.1.2 is the line $p = q$ which would result if the reciprocal-lattice point were a rectangular block whose surfaces were parallel and perpendicular to the Ewald sphere at the point of penetration.

Assuming a right-handed coordinate system (x, y, z) in reciprocal space fixed to the camera, it is easily shown (Wonacott, 1977) that the condition for reflection is

$$d^{*2} + (2z/\lambda) = 0, \qquad \text{(A11.5.1.2)}$$

where d^* is the distance of a reciprocal-lattice point $P(x, y, z)$ from the origin, O, of reciprocal space. Similarly, it can be shown that at the ends of the path of the reciprocal-lattice point through the finite thickness of the sphere,

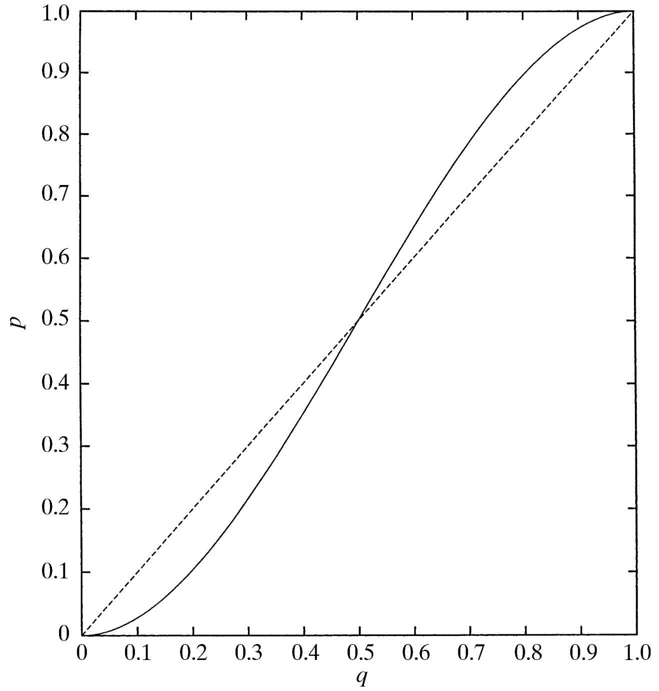

Figure A11.5.1.2
Relationship between the fraction of the path travelled, q, by a reciprocal-lattice point across an Ewald sphere of finite thickness and the fraction of the total scattered intensity, p. The curve shown is for $p = 3q^2 - 2q^3$. As an extreme case, the line $p = q$ is also shown.

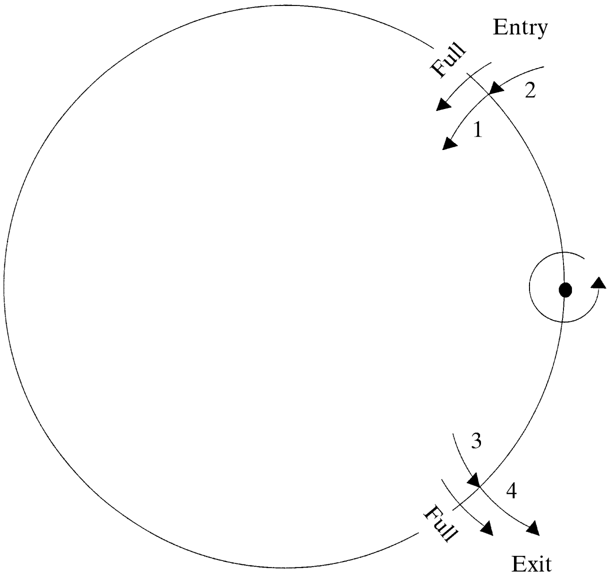

Figure A11.5.1.3
The four conditions 1, 2, 3 and 4 for partial reflections corresponding to Table A11.5.1.1. The arrow ends and heads correspond to the start and end positions of a reciprocal-lattice point, respectively.

$$\begin{aligned} &d^{*2} + \delta^2 + (2z/\lambda) - 2\delta\left(x_A^2 + y_A^2\right)^{1/2} = 0 \quad \text{and} \\ &d^{*2} + \delta^2 + (2z/\lambda) - 2\delta\left(x_B^2 + y_B^2\right)^{1/2} = 0. \end{aligned} \qquad \text{(A11.5.1.3)}$$

Therefore,

$$\begin{aligned} z_A &= (\lambda/2)\left[-d^{*2} - \delta^2 + 2\delta\left(x_A^2 + y_A^2\right)^{1/2}\right], \\ z_B &= (\lambda/2)\left[-d^{*2} - \delta^2 + 2\delta\left(x_B^2 + y_B^2\right)^{1/2}\right]. \end{aligned} \qquad \text{(A11.5.1.4)}$$

Since δ is small, it can be assumed that $2\delta(x^2 + y^2)^{1/2}$ is independent of the position of the reciprocal-lattice point P between the extreme positions P_A and P_B (Fig. A11.5.1.1). Hence, the length of the path through the finite thickness of the sphere is proportional to

$$z_A - z_B = 2\lambda\delta\left(x_P^2 - y_P^2\right)^{1/2}. \qquad \text{(A11.5.1.5)}$$

Now, if a reflection is only just penetrating the sphere at the end of the oscillation range, then the fraction of penetration is given by

$$q = PP_A/P_AP_B = (z_P - z_A)/(z_B - z_A). \qquad \text{(A11.5.1.6)}$$

Substituting this expression into equation (A11.5.1.4), it follows that

$$q = \tfrac{1}{2}\left[1 + (D_1/\eta_1)\right], \qquad \text{(A11.5.1.7)}$$

where

$$D = d^{*2} + \delta^2 + (2z/\lambda) \qquad \text{(A11.5.1.8)}$$

and

$$\eta = 2\delta(x^2 + y^2)^{1/2}. \qquad \text{(A11.5.1.9)}$$

The subscripts A and B refer to the beginning and end of the oscillation range for the partial reflection P, respectively.

Similarly, if a reflection is almost completely within the sphere,

$$q = PP_B/P_AP_B = (z_B - z_P)/(z_B - z_A) = \tfrac{1}{2}\left[1 - (D_2/\eta_2)\right]. \qquad \text{(A11.5.1.10)}$$

There are indeed four such conditions: two while a reflection is entering the Ewald sphere, and two while it is exiting. As such, it is readily seen that $-1 < (D_i/\eta_i) < 1$ ($i = 1$ or 2) is the range for a partial reflection. The full range of conditions is given in Table A11.5.1.1, as are the conditions for a full reflection.

This article is based primarily on the original publication by Bolotovsky *et al.* (1998). We are grateful for an NSF Grand Challenge grant in support of this work.
